In the past, specific diagnostic tests for coronavirus infections were not available in most clinical settings. The use of conserved PCR primers for coronaviruses in multiplex RT-PCR viral diagnostic panels now allows widely available and sensitive detection of the viruses. Virus culture of primary clinical specimens remains a challenge for HCoV’s HKU1, OC43, 229E, and NL63, even though both SARS-CoV and MERS-CoV can successfully be grown in culture from respiratory samples. Serodiagnosis with complement fixation, neutralization, hemagglutination inhibition, enzyme immunoassay, and Western blots have been used in the research setting. The diagnosis of SARS-CoV infection can be confirmed by serologic testing, detection of viral RNA using RT-PCR, or isolation of the virus in cell culture. Even though serology for SARS-CoV has sensitivity and specificity approaching 100%, antibodies are not detectable until 10 days after the onset of symptoms, and immunoglobulin G seroconversion may be delayed for up to 4 wk. In addition, the SARS epidemic resulted in the inclusion of coronavirus-conserved primers in many diagnostic PCR multiplex assays such that coronaviruses may be more readily detected. For emerging coronaviruses, such as HCoV-EMC, highly conserved primers were used for initial detection, with confirmatory assays using specific primers. Thus, the mainstay of early diagnosis is RT-PCR. For all known endemic and emerging HCoVs, respiratory specimens (nasopharyngeal swabs or aspirates) are most likely to be positive, but in a setting of a possible novel coronavirus, serum or stool may be positive. Two highly sensitive real-time RT-PCR assays are currently available for testing for MERS-CoV RNA in addition to utilizing immunofluorescence microscopy for the detection of antibody response.

**TREATMENT AND PREVENTION**

Coronavirus infections of humans are acute and self-limited, although persistent infection and shedding may occur in multiple animal models in the setting of minimal or no symptomology. There are no available antiviral agents for clinical use against coronaviruses, although strategies targeting conserved coronavirus proteases have been shown to block replication of the virus in vitro. Challenges for development of effective vaccines targeted against OC43, 229E, HKU1, and NL63 include the fact that infections are rarely life-threatening and reinfection is the rule, even in the presence of natural immunity from previous infections. Treatment of SARS-CoV and MERS-CoV infections is primarily supportive. The role of antiviral and immune-modulating...
agents remains inconclusive, largely because none of these therapies have been evaluated in properly conducted randomized controlled trials. Ribavirin was extensively used during the 2003 SARS-CoV outbreak, but is of questionable benefit given its poor in vitro activity against SARS-CoV at clinically relevant concentrations. The identification of the proofreading nsp14-exonuclease suggests that this activity may be important in resistance to antiviral nucleosides and RNA mutagens such as ribavirin. Systemic corticosteroid therapy was temporally associated with clinical improvement in some patients. In another small, open-label, nonrandomized pilot study, interferon-α was associated with more rapid resolution of oxygen requirements and radiographic abnormalities. Human monoclonal antibodies derived from SARS patients demonstrate broad neutralization against early and late epidemic strains of SARS-CoV and could potentially be therapeutic.

An effective vaccine for SARS-CoV and MERS-CoV is highly desirable but not yet available. A potential vaccine target is the viral spike protein, which could be delivered as a recombinant protein or via viral or DNA vectors. This approach appears to be effective against closely related strains of SARS-CoV but not necessarily early animal or human variants. A SARS-CoV vaccine approach that recently has shown success in animal models utilized a live-engineered SARS-CoV mutant with inactivated ExoN, demonstrating attenuation and protection in a variety of aged, immunocompromised mice. Approaches for rapid development of stably attenuated live viruses or broadly immunogenic and cross-protective protein immunogens continues to be a key area for future research. Although SARS-CoV demonstrated characteristics of symptomatic transmission that made it controllable by public health measures like quarantine, these characteristics cannot be assumed for future novel HCoVs. The recent outbreak of MERS-CoV serves as a reminder that coronavirus emergence is both likely and unpredictable, making it very important to continue studies of the coronavirus replication, emergence, and transmission of coronaviruses. Additionally, strategies for rapid recovery, testing, and development of vaccines and neutralizing human monoclonal antibodies may be essential to prevent the high morbidity and mortality associated with previous epidemics.

Bibliography

Diarrhea is a leading cause of childhood mortality in the world, accounting for 5-10 million deaths/yr. In early childhood, the single most important cause of severe dehydrating diarrhea is rotavirus infection. Rotavirus and other gastroenteric viruses not only are major causes of pediatric mortality but also lead to significant morbidity. Children in the United States, before vaccine was available, were estimated to have a risk of hospitalization for rotavirus diarrhea of 1:43, corresponding to 80,000 hospitalizations annually.

**ETIOLOGY**

Rotaviruses, astroviruses, caliciviruses such as the Norwalk agent, and enteric adenoviruses are the medically important pathogens of human viral gastroenteritis (see Chapter 340).

Rotaviruses are in the Reoviridae family and cause disease in virtually all mammals and birds. These viruses are wheel-like, triple-shelled icosahedrons containing 11 segments of double-stranded RNA. The diameter of the particles on electron microscopy is approximately 80 nm. Rotaviruses are classified by serogroup (A, B, C, D, E, F, and G) and subgroup (1 or II). Rotavirus strains are species specific and do not cause disease in heterologous hosts. Group A includes the common human pathogens as well as a variety of animal viruses. Group B rotavirus is reported as a cause of severe disease in infants and adults in China only. Occasional human outbreaks of group C rotavirus are reported. The other serogroups infect only nonhumans.

Subgrouping of rotaviruses is determined by the antigenic structure of the inner capsid protein, VP6. Serotyping of rotaviruses, described for group A only, is determined by classic cross-neutralization testing and depends on the outer capsid glycoproteins, VP7 and VP4. The VP7 serotype is referred to as the G type (for glycoprotein). There are 10 G serotypes, of which 4 cause most illness and vary in occurrence from year to year and region to region. The VP4 serotype is referred to as the P type. There are 11 P serotypes. Although both VP4 and VP7 elicit neutralizing immunoglobulin G antibodies, the relative role of these systemic antibodies compared with that of mucosal immunoglobulin A antibodies and cellular responses in protective immunity remains unclear.

Caliciviruses, which constitute the Caliciviridae family, are small 27-35 nm viruses that are the most common cause of gastroenteritis outbreaks in older children and adults. Caliciviruses also cause a rotavirus-like illness in young infants. They are positive-sense, single-stranded RNA viruses with a single structural protein. Human caliciviruses are divided into 2 genera, the noroviruses and sapoviruses. Caliciviruses have been named for locations of initial outbreaks: Norwalk, Snow Mountain, Montgomery County, Sapporo, and others. Caliciviruses and astroviruses are sometimes referred to as small, round viruses on the basis of appearance on electron microscopy.

Astroviruses, which constitute the Astroviridae family, are important agents of viral gastroenteritis in young children, with a high incidence in both the developing and developed worlds. Astroviruses are positive-sense, single-stranded RNA viruses. They are small particles, approximately 30 nm in diameter, with a characteristic central 5- or 6-pointed star when viewed on electron microscopy. The capsid consists of 3 structural proteins. There are 8 known human serotypes.

Enteric adenoviruses are a common cause of viral gastroenteritis in infants and children. Although many adenovirus serotypes exist and are found in human stool, especially during and after typical upper respiratory tract infections (see Chapter 262), only serotypes 40 and 41 cause gastroenteritis. These strains are very difficult to grow in tissue culture. The virus consists of an 80 nm-diameter icosahedral particle with a relatively complex double-stranded DNA genome.

Aichi virus is a picornavirus that is associated with gastroenteritis and was initially described in Asia. Several other viruses that may cause diarrheal disease in animals have been postulated but are not well established as human gastroenteritis viruses. These include coronaviruses, toroviruses, and pestiviruses. The picobirnaviruses are an unclassified group of small (30 nm), single-stranded RNA viruses that have been found in 10% of patients with HIV-associated diarrhea.

**EPIDEMIOLOGY**

Worldwide, rotavirus is estimated to cause more than 111 million cases of diarrhea annually in children younger than 5 yr of age. Of these, 18 million cases are considered at least moderately severe, with approximately 500,000 deaths per year. Rotavirus causes 3 million cases of diarrhea, 80,000 hospitalizations, and 20–40 deaths annually in the United States.

Rotavirus infection is most common in winter months in temperate climates. In the United States, the annual winter peak historically spread from west to east. Unlike the spread of other winter viruses, such as influenza, this wave of increased incidence was not caused by a single prevalent strain or serotype. Since widespread adoption of vaccine, this geographic phenomenon has vanished. Typically, several serotypes predominate in a given community for 1 or 2 seasons, while nearby locations may harbor unrelated strains. Disease tends to be most severe in patients 3–24 mo of age, although 25% of the cases of severe disease occur in children older than 2 yr of age, with serologic evidence of infection developing in virtually all children by 4-5 yr of age. Infants younger than 3 mo are relatively protected by transplacental antibody and possibly breastfeeding. Infections in neonates and in adults in close
contact with infected children are generally asymptomatic. Some rotavirus strains have stably colonized newborn nurseries for years, infecting virtually all newborns without causing any overt illness.

Rotavirus and the other gastrointestinal viruses spread efficiently via a fecal-oral route, and outbreaks are common in children's hospitals and childcare centers. The virus is shed in stool at very high concentration before and for days after the clinical illness. Very few infectious virions are needed to cause disease in a susceptible host.

The epidemiology of astroviruses is not as thoroughly studied as that of rotavirus, but these viruses are a common cause of mild to moderate watery winter diarrhea in children and infants and an uncommon pathogen in adults. Hospital outbreaks are common. Enteric adenovirus gastroenteritis occurs year-round, mostly in children younger than 2 yr of age. Nosocomial outbreaks occur but are less common than with rotavirus and astrovirus. Calicivirus is best known for causing large, explosive outbreaks among older children and adults, particularly in settings such as schools, cruise ships, and hospitals. Often a single food, such as shellfish or water used in food preparation, is identified as a source. Like astrovirus and rotavirus, caliciviruses are also commonly found in winter infantile gastroenteritis.

PATHOGENESIS
Viruses that cause human diarrhea selectively infect and destroy villus tip cells in the small intestine. Biopsies of the small intestines show variable degrees of villus blunting and round cell infiltrate in the lamina propria. Pathologic changes may not correlate with the severity of clinical symptoms and usually resolve before the clinical resolution of diarrhea. The gastric mucosa is not affected despite the commonly used term gastroenteritis, although delayed gastric emptying has been documented during Norwalk virus infection.

In the small intestine, the upper villus enterocytes are differentiated cells, which have both digestive functions, such as hydrolysis of disaccharides, and absorptive functions, such as the transport of water and electrolytes via glucose and amino acid cotransporters. Crypt enterocytes are undifferentiated cells that lack the brush-border hydrolytic enzymes and are net secretors of water and electrolytes. Selective viral infection of intestinal villus tip cells thus leads to (1) decreased absorption of salt and water and an imbalance in the ratio of intestinal fluid absorption to secretion, and (2) diminished disaccharidase activity and malabsorption of complex carbohydrates, particularly lactose. Most evidence supports altered absorption as the more important factor in the genesis of viral diarrhea. It has been proposed that a rotavirus nonstructural protein (NSP4) functions as an enterotoxin.

Viremia may occur often in severe, primary infections, but symptomatic extraintestinal infection is extremely rare in immunocompetent persons—although immunocompromised patients may rarely experience hepatic and renal involvement. The increased vulnerability of infants (compared with older children and adults) to severe morbidity and mortality from gastroenteritis viruses may relate to a number of factors, including decreased intestinal reserve function, lack of specific immunity, and decreased nonspecific host defense mechanisms such as gastric acid and mucus. Viral enteritis greatly enhances intestinal permeability to luminal macromolecules and has been postulated to increase the risk for food allergies.

CLINICAL MANIFESTATIONS
Rotavirus infection typically begins after an incubation period of <48 hr (range: 1-7 days) with mild to moderate fever as well as vomiting, followed by the onset of frequent, watery stools. All 3 symptoms are present in about 50-60% of cases. Vomiting and fever typically abate during the 2nd day of illness, but diarrhea often continues for 5-7 days. The stool is without gross blood or white blood cells. Dehydration may develop and progress rapidly, particularly in infants. The most severe disease typically occurs among children 4-36 mo of age. Malnourished children and children with underlying intestinal disease, such as short-bowel syndrome, are particularly likely to acquire severe rotavirus diarrhea. Rarely, immunodeficient children experience severe and prolonged illness. Although most newborns infected with rotavirus are asymptomatic, some outbreaks of necrotizing enterocolitis have been associated with the appearance of a new rotavirus strain in the affected nurseries.

The clinical course of astrovirus infection appears to be similar to that of rotavirus gastroenteritis, with the notable exception that the disease tends to be milder, with less significant dehydration. Adenovirus enteritis tends to cause diarrhea of longer duration, often 10-14 days. The Norwalk virus has a short (12-hr) incubation period. Vomiting and nausea tend to predominate in illness associated with the Norwalk virus, and the duration is brief, usually consisting of 1-3 days of symptoms. The clinical and epidemiologic picture of Norwalk virus often closely resembles so-called food poisoning from preformed toxins such as Staphylococcus aureus and Bacillus cereus.

DIAGNOSIS
In most cases, a satisfactory diagnosis can be made on the basis of the clinical and epidemiologic features. Enzyme-linked immunosorbent assays, which offer >90% specificity and sensitivity, are available for detection of group A rotavirus, caliciviruses, and enteric adenovirus in stool samples. Latex agglutination assays are also available for group A rotavirus and are less sensitive than enzyme-linked immunosorbent assay. Research tools include electron microscopy of stools, RNA polymerase chain reaction analysis to identify G and P antigens, and culture. The diagnosis of viral gastroenteritis should always be questioned in patients with persistent or high fever, blood or white blood cells in the stool, or persistent severe or bilious vomiting, especially in the absence of diarrhea.

LABORATORY FINDINGS
Isotonic dehydration with acidosis is the most common finding in children with severe viral enteritis. The stools are free of blood and leukocytes. Although the white blood cell count may be moderately elevated secondary to stress, the marked left shift seen with invasive bacterial enteritis is absent.

DIFFERENTIAL DIAGNOSIS
The differential diagnosis includes other infectious causes of enteritis, such as bacteria and protozoa. Occasionally, surgical conditions such as appendicitis, bowel obstruction, and intussusception may initially mimic viral gastroenteritis.

TREATMENT
Avoiding and treating dehydration are the main goals in treatment of viral enteritis. A secondary goal is maintenance of the nutritional status of the patient (see Chapters 58 and 340).

There is no routine role for antiviral drug treatment of viral gastroenteritis. Controlled studies show no benefit from antiemetics or anti-diarrheal drugs, and there is a significant risk for serious side effects with both types of agents. Antibiotics are similarly of no benefit. Immunoglobulins have been administered orally to both normal and immunodeficient patients with severe rotavirus gastroenteritis, but this treatment is currently considered experimental. Therapy with probiotic organisms such as Lactobacillus species has been shown to be helpful only in mild cases and not in dehydrating disease.

Supportive Treatment
Rehydration via the oral route can be accomplished in most patients with mild to moderate dehydration (see Chapters 58 and 340). Severe rehydration requires immediate intravenous therapy followed by oral rehydration. Modern oral rehydration solutions containing appropriate quantities of sodium and glucose promote optimum absorption of fluid from the intestine. There is no evidence that a particular carbohydrate source (rice) or addition of amino acids improves the efficacy of these solutions for children with viral enteritis. Other clear liquids, such as flat soda, fruit juice, and sports drinks, are inappropriate for rehydration of young children with significant stool loss. Rehydration via the oral (or nasogastric) route should be done over 6-8 hr, and feedings should be initiated immediately thereafter. Providing the rehydration fluid at a slow, steady rate, typically 5 mL/min, reduces vomiting and improves the success of oral therapy. Rehydration...
solution should be continued as a supplement to make up for ongoing excessive stool loss. Initial intravenous fluids are required for the infant in shock or the occasional child with intractable vomiting.

After rehydration has been achieved, resumption of a normal diet for age has been shown to result in a more rapid recovery from viral gastroenteritis. Prolonged (>12 hr) administration of exclusive clear liquids or dilute formula is without clinical benefit and actually prolongs the duration of diarrhea. Breastfeeding should be continued even during rehydration. Selected infants may benefit from lactose-free feedings (such as soy formula and lactose-free cow’s milk) for several days, although this step is not necessary for most children. Hypocaloric diets low in protein and fat such as BRAT (bananas, rice, cereal, applesauce, and toast) have not been shown to be superior to a regular diet.

**PROGNOSIS**

Most fatalities occur in infants with poor access to medical care and are attributed to dehydration. Children may be infected with rotavirus each year during the 1st 5 yr of life, but each subsequent infection decreases in severity. Primary infection results in a predominantly serotype-specific immune response, whereas reinfection, which is usually with a different serotype, induces a broad immune response with cross-reactive heterotypic antibody. After the initial natural infection, children have limited protection against subsequent asymptomatic infection (38%) and greater protection against mild diarrhea (73%) and moderate to severe diarrhea (87%). After the second natural infection, protection increases against subsequent asymptomatic infection (62%) and mild diarrhea (75%) and is complete (100%) against moderate to severe diarrhea. After the third natural infection, there is even higher protection against subsequent asymptomatic infection (74%) and near-complete protection against even mild diarrhea (99%).

**PREVENTION**

Good hygiene reduces the transmission of viral gastroenteritis, but even in the most hygienic societies, virtually all children become infected as a result of the efficiency of infection of the gastroenteritis viruses. Good handwashing and isolation procedures can help control nosocomial outbreaks. The role of breastfeeding in prevention or amelioration of rotavirus infection may be small, given the variable protection observed in a number of studies. Vaccines offer the best hope for control of these ubiquitous infections.

**Vaccines**

A trivalent rotavirus vaccine was licensed in the United States in 1998 and was subsequently linked to an increased risk for intussusception, especially during the 3-14 day period after the 1st dose and the 3-7 day period after the 2nd dose. The vaccine was withdrawn from the market in 1999. Subsequently 2 new live, oral rotavirus vaccines have been approved in the United States after extensive safety and efficacy testing.

A live, oral, pentavalent rotavirus vaccine was approved in 2006 for use in the United States. The vaccine contains 5 reassortant rotaviruses isolated from human and bovine hosts. Four of the reassortant rotaviruses express 1 serotype of the outer protein VP7 (G1, G2, G3, or G4), and the 5th expresses the protein P1A (genotype P[8]) from the human rotavirus parent strain. The pentavalent vaccine protects against rotavirus gastroenteritis when administered as a 3 dose series at 2, 4, and 6 mo of age. The 1st dose should be administered between 6 and 12 wk of age, with all 3 doses completed by 32 wk of age. The vaccine provides substantial protection against rotavirus gastroenteritis, with primary efficacy of 98% against severe rotavirus gastroenteritis caused by G1-G4 serotypes and 74% efficacy against rotavirus gastroenteritis of any severity through the first rotavirus season after vaccination. It provides a 96% reduction in hospitalizations for rotavirus gastroenteritis through the 1st 2 yr after the 3rd dose. In a study of more than 70,000 infants, the pentavalent vaccine did not increase the risk for intussusception, although other studies suggest a slight increased risk.

Another new monovalent rotavirus vaccine was licensed in the United States and also appears to be safe and effective. It is an attenuated monovalent human rotavirus and is administered as 2 oral doses at 2 and 4 mo of age. The vaccine has 85% efficacy against severe gastroenteritis and was found to reduce hospital admissions for all diarrhea by 42%. Despite being monovalent, the vaccine is effective in prevention of all 4 common serotypes of human rotavirus.

Preliminary surveillance data on rotavirus incidence from the U.S. Centers for Disease Control and Prevention suggest that rotavirus vaccination greatly reduced the disease burden in the United States during the 2007-2008 rotavirus season. Given the incomplete vaccine coverage during this period, the results suggest a degree of “herd immunity” from rotavirus immunization. Studies from several developed countries show greater than 90% protection against severe rotavirus disease. Studies from developing countries show 50-60% protection from severe disease. Vaccine-associated disease has been reported in vaccine recipients who have severe combined immunodeficiency disease (a contraindication). In addition, vaccine-derived virus may undergo reassortment and become more virulent, producing diarrhea in unvaccinated siblings.

*Bibliography is available at Expert Consult.*
Bibliography

Human papillomaviruses (HPVs) cause a variety of proliferative cutaneous and mucosal lesions, including common skin warts, benign and malignant anogenital tract lesions, oral pharyngeal cancers, and life-threatening respiratory papillomas. Most HPV-related infections in children and adolescents are benign.

**ETIOLOGY**
The papillomaviruses are small (55 nm), DNA-containing viruses that are ubiquitous in nature, infecting most mammalian and many non-mammalian animal species. Strains are almost always species specific. More than 100 different types of HPVs have been identified through comparison of sequence homologies. The different HPV types typically cause disease in specific anatomic sites; more than 30 HPV types have been identified from genital tract specimens.

**EPIDEMIOLOGY**
HPV infections of the skin are common, and most individuals are probably infected with 1 or more HPV types at some time. There are no animal reservoirs for HPV; all transmission is presumably from person to person. There is little evidence to suggest that HPV is transmitted by fomites. Common warts, including palmar and plantar warts, are frequently seen in children and adolescents and typically infect the hands and feet, common areas of frequent minor trauma.

Human papillomavirus is the most prevalent viral sexually transmitted infection in the United States. Up to 80% of sexually active women will acquire HPV through sexual transmission; most have their first infection within 3 yr of beginning sexual intercourse. The greatest risks for HPV in sexually active adolescents is exposure to new sexual partners or having more than 1 partner, underscoring the ease of transmission of this virus through sexual contact. It is estimated that after 11 acts of sexual intercourse 100% of all HPV types will be transmitted to the other sexual partner. Couple studies show that there is high concordance in the genital area as well as between the hand and the genital area in the other partner. Whether the DNA detected in the hand is capable of transmitting infectious particles is unknown. Unlike other sexually transmitted infections, female-to-male transmission appears greater than male-to-female transmission. This may be because males in general have superficial transient infections or deposition. In turn, males do not develop an adequate immune response, so reinfections
are quite common. The prevalence of HPV in women decreases with time, suggesting immune protection, whereas in men, the prevalence of HPV remains high across all ages.

As with many other genital pathogens, perinatal transmission to newborns also occurs, but infections appear transient. Transmission from caregiver to the child during the early childhood years has also been documented but is generally transient, as with perinatal detection. It remains unclear whether these HPV DNA detections are simply deposition of caregiver DNA or true infections. Detection of HPV DNA in older preadolescent children is rare. HPV DNA detection in nonsexually active adolescents has been reported, but the reports of no sexual activity in adolescent populations can be difficult to confirm. If lesions are detected in a child older than 3 yr of age, the possibility of sexual transmission should be raised.

In adolescents, HPV DNA is most commonly detected without evidence of any lesion. Some of these detections are thought to be the result of partner deposition and hence do not represent a true infection. In older women, detection of HPV DNA is more commonly associated with a lesion. This is because the HPV DNA detected in older women reflects those HPV infections that became established persistent infections. Persistence is now the known necessary prerequisite for the development of significant precancerous lesions and cervical cancer. Approximately 15-20% of sexually active adolescents have detectable HPV at any given time and have normal cytologic findings. External genital warts are much less common, occurring in <1% of adolescents. The most common clinically detected lesion in adolescent women is the cervical lesion termed low-grade squamous intraepithelial lesion (LSIL) (Table 266-1). LSILs can be found in 25-30% of adolescents infected with HPV. LSIL is a cytologic and histologic term to reflect the benign changes caused by an active viral infection and is likely present in most, if not all, women with HPV infection. The majority of women, however, have very minute or subtle lesions not easily detected by cytology. As with HPV DNA detection, most LSILs regress spontaneously in young women and do not require any intervention or therapy. Less commonly, HPV can induce more severe cellular changes, termed high-grade squamous intraepithelial lesions (HSILs) (see Chapter 553).

Although HSILs are considered precancerous lesions, they rarely progress to invasive cancer. HSILs occur in approximately 0.4-3% of sexually active women, whereas invasive cervical cancer occurs in 8 cases per 100,000 adult women. In true virginal populations, including children who are not sexually abused, rates of clinical disease are close to zero. In the United States, there are approximately 12,000 new cases and 3,700 deaths from cervical cancer each year. Worldwide, cervical cancer is the second most common cause of cancer deaths among women.

Some infants may acquire papillomaviruses during passage through an infected birth canal, leading to recurrent juvenile laryngeal papillomatosis (also referred to as respiratory papillomatosis). Cases also have been reported after cesarean section. The incubation period for emergence of clinically apparent lesions (genital warts or laryngeal papillomas) after perinatally acquired infection is unknown but is estimated to be around 3-6 mo (see Chapter 390.2). It may be that infections can also occur during hygienic care from an infected parent.

Genital warts appearing in childhood may result from sexual abuse, with HPV transmission during the abusive contact. Genital warts may represent a sexually transmitted infection even in some very young children. Their presence is cause to suspect that possibility. A child with genital warts should therefore be provided with a complete evaluation for evidence of possible abuse (see Chapter 40.1), including the presence of other sexually transmitted infections (see Chapter 120). Presence of genital warts in a child does not confirm sexual abuse, because perinatally transmitted genital warts may go undetected until the child is older. Typing for specific genital HPV types in children is not helpful in diagnosis or to confirm sexual abuse status, because the same genital types occur in both perinatal transmission and abuse.

**PATHOGENESIS**

Initial HPV infection of the cervix is thought to begin by viral invasion of the basal cells of the epithelium, a process that is enhanced by disruption of the epithelium caused by trauma or inflammation. It is thought that the virus initially remains relatively dormant because virus is present without any evidence of clinical disease. The life cycle of HPV depends on the differentiation program of keratinocytes. The pattern of HPV transcription varies throughout the epithelial layer as well as through different stages of disease (LSIL, HSIL, invasive cancer). Understanding of HPV transcription enhances understanding of its ability to behave as an oncovirus. Early region proteins, E6 and E7, function as transactivating factors that regulate cellular transformation. Complex interactions between E6- and E7-transcribed proteins and host proteins result in the perturbation of normal processes that regulate cellular DNA synthesis. The perturbations caused by E6 and E7 are primarily disruption of the antioncoprotein p53 and retinoblastoma protein (Rb), respectively, contributing to the development of anogenital cancers. Disruption of these proteins results in continued cell proliferation, even under the circumstances of DNA damage, which leads to basal cell proliferation, chromosomal abnormalities.

NOS, not otherwise specified.
and aneuploidy, hallmarks of squamous intraepithelial lesion (SIL) development.

Evidence of productive viral infection occurs in benign lesions such as external genital warts and LSILs, with the abundant expression of viral capsid proteins in the superficial keratinocytes. The appearance of the HPV-associated koilocyte is a result of the expression of E4, a structural protein that causes collapse of the cytoskeleton. Low-level expression of E6 and E7 proteins results in cell proliferation seen in the basal cell layer of LSILs. LSILs are a manifestation of active viral replication and protein expression. In HSILs, expression of E6 and E7 predominates throughout the epithelium with little expression of the structural proteins L1 and L2. This results in the chromosomal abnormalities and aneuploidy characteristic of the higher-grade lesions. The critical events that lead to cancer have not been verified; however, several mechanisms are thought to be critical, including viral integration into the host chromosome and activation of telomerase to lengthen chromosomes and avoid physiologic cell senescence. Over 150 HPV types have been documented and are classified by extent of their DNA homology into 5 genera, with different types having different life-cycle and disease characteristics. The predominant group is α HPV types, which are associated with cutaneous and mucosal anogenital infections and cancers. β, γ, μ, and ν types are commonly detected in the skin without any apparent lesions but are associated with the development of skin cancers in those with epidermodysplasia verruciformis or other forms of immunodeficiencies. Genital lesions caused by the α HPV types may be broadly grouped into those with little to no malignant potential (low risk) and those with greater malignant potential (high risk). Low-risk HPV types 6 and 11 are most commonly found in genital warts and are rarely found isolated in malignant lesions. High-risk HPV types are those that are associated with anogenital cancers, specifically cervical cancer. HPV 16 and 18 are thought to be more oncogenic than other HPV types because they comprise 70% of cervical cancers, whereas each of the other 13 high-risk types (31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, and 73) contributes less than 1-9%. HPV 16 appears to be even more important in anal and HPV-associated oropharyngeal cancers, comprising close to 90% of these cancers. HPV 16 is also commonly found in women without lesions or in those with LSILs, making the connection with cancer confusing. Genital warts and SIL are commonly associated with the detection of multiple HPV types, including a combination of low- and high-risk HPV types. Recent data show that it is likely that a single lesion arises from a single HPV type. Detection of multiple HPV types reflects the presence of cervical and anal coexisting lesions. Almost all (95%) incident low-risk and high-risk HPV DNA detection, with or without detectable SIL, will spontaneously resolve within 1-3 yr. Although HPV 16 has a slower rate of regression than some of the other high-risk types, the majority of incident HPV 16 detection also will resolve. Data suggest that clearance of an HPV type results in natural immune protection against reinfection with that same type. Redetections of the same type are not common and when found are often associated with a history of a new sexual partner, suggesting that these are not reactivated infections but are due to new exposures. These redetections rarely result in high-grade disease. Persistent high-risk–type infections are associated with increased risk for development of HSILs and invasive cancer. Progression of HSIL to invasive cancer is still rare, with only 5-15% showing progression. Approximately 50% of HPV 16–associated HSILs and 80% of non–HPV 16 HSILs will spontaneously regress in young women. Genital and common warts in general also resolve without therapy but may take years to do so. Genital warts in only extremely rare conditions can become malignant.

Most infants with recognized genital warts are infected with the low-risk types. In contrast, children with a history of sexual abuse have a clinical picture more like that of adult genital warts, consisting of mixed low- and high-risk types. There are rare reports of HPV-associated genital malignancies occurring in preadolescent children and adolescents. On the other hand, precancerous HSILs do occur in sexually active adolescents. There is a concern that younger age of sexual debut has contributed to the increase in invasive cervical cancers seen in women younger than 50 yr of age in the United States, specifically cervical adenocarcinomas. Persistent HPV infections are considered necessary but not sufficient for the development of invasive cancers. Other risk factors for which there is relatively strong suggestive evidence of association include smoking cigarettes, prolonged oral contraceptive use, greater parity, and Chlamydia trachomatis and herpes simplex virus infections.

**CLINICAL MANIFESTATIONS**
The clinical findings in HPV infection depend on the site of epithelial infection.

**Skin Lesions**
The typical HPV-induced lesions of the skin are proliferative, papular, and hyperkeratotic. Common warts are raised circinate lesions with a keratinized surface (Fig. 266-1). Plantar and palmar warts are practically flat. Multiple warts are common and may create a mosaic pattern. Flat warts appear as small (1-5 mm), flat, flesh-colored papules.

**Genital Warts**
Genital warts may be found throughout the perineum around the anus, vagina, and urethra, as well as in the cervical, intravaginal, and intraanal areas (Fig. 266-2). Intraanal warts occur predominantly in patients who have had receptive anal intercourse, in contrast with perianal warts, which may occur in men and women without a history of anal sex. Although rare, lesions caused by genital genotypes can also be found on other mucosal surfaces, such as the conjunctivae, tongue, gingivae, and nasal mucosa. They may be single or multiple lesions and are frequently found in multiple anatomic sites, including the cervix. External genital warts can be flat, dome shaped, keratotic, pedunculated, and cauliflower shaped and may occur singly, in clusters, or as plaques. On mucosal epithelium, the lesions are softer. Depending on the size and anatomic location, lesions may be pruritic and painful, may cause burning with urination, may be friable and bleed, or may become superinfected. Adolescents are frequently disturbed by the development of genital lesions. Other rarer lesions caused by HPV of the external genital area include Bowen disease, Bowenoid papulosis, squamous cell carcinomas, Buschke-Löwenstein tumors, and vulvar intraepithelial neoplasias.

**Squamous Intraepithelial Lesions and Cancers**
Squamous intraepithelial lesions detected with cytology are usually invisible to the naked eye and require the aid of colposcopic magnification and acetic acid. With aid, the lesions appear white and show evidence of neovascularity. SILs can occur on the cervix, vagina, vulva, penis, and intraanus. Invasive cancers tend to be more exophytic, with aberrant-appearing vasculature. These lesions are rarely found in nonsexually active individuals.

![Figure 266-1 Common warts of the left hand and the chest wall. (From Meneghini CL, Bonifaz E: An atlas of pediatric dermatology, Chicago, 1986, Year Book Medical Publishers, p. 45.)](image-url)
Laryngeal Papillomatosis

The median age at diagnosis of recurrent laryngeal papillomatosis is 3 yr. Children present with hoarseness, an altered cry, and sometimes stridor. Rapid growth of respiratory papillomas can occlude the upper airway, causing respiratory compromise. These lesions may recur within weeks of removal, requiring frequent surgery. The lesions do not become malignant unless treated with irradiation.

DIAGNOSIS

The diagnosis of external genital warts and common warts may be reliably determined by visual inspection of a lesion by an experienced observer and does not require additional tests for confirmation. A biopsy should be considered if the diagnosis is uncertain, the lesions do not respond to therapy, or the lesions worsen during therapy.

Screening for cervical cancer in young women begins with cytology, which is either performed by Papanicolaou smear or liquid-based cytology. Screening guidelines, which were updated in 2012 by the American Cancer Society and the U.S. Preventive Services Task Force, recommend to start screening at age 21 yr. Screening earlier is more likely to result in unnecessary referrals for colposcopy, because most lesions, both LSILs and HSILs in this group, are likely to regress. Updated guidelines now recommend screening with cytology every 3 yr. At 30 yr of age, screening can also include cotesting with HPV DNA. This is not recommended earlier, because HPV infections are extremely common in young women, resulting in a very-low positive-predictive value in this age group. The recommended terminology used for cytologic evaluation is based on the Bethesda system (see Table 266-1). Recent updates to terminology used for histology uses similar terms. Many clinicians still prefer the World Health Organization terminology using cervical intraepithelial neoplasia (CIN) 1, 2, and 3 (see Table 266-1). Although the purpose of screening is to identify CIN 3+ lesions, the majority of these lesions are found in women who were referred for atypical squamous cells of undetermined significance (ASC-US) or LSILs on cytology. On the other hand, few CIN 3 or cancers exist in women younger than 24 yr of age. For women 21-24 yr of age, ASC-US and LSILs are treated the same. The current preferred recommendation for young women with ASC-US or LSILs is to repeat cytology every 12 mo for up to 24 mo. For persistent ASC-US or LSILs at 2 yr of follow-up, referral for colposcopy is recommended. Women 21-24 yr of age with HSIL at any visit should be referred for colposcopy and biopsy. In adult women, HSIL can be treated without histologic confirmation. However, this approach should be avoided in those 21-24 yr of age, because HSIL is often misdiagnosed in this group or will resolve spontaneously.

In women older than 21 yr of age, high-risk HPV testing is acceptable to assist in ASC-US triage. This recommendation is based on the observations that adult women with ASC-US and a positive HPV test result for high-risk types are more likely to have CIN 2/3 than women with a negative HPV test result. However, in women with ASC-US and a positive HPV test for high-risk types, repeat cytology is recommended. In women 21-24 yr of age referred for colposcopy and found to have no lesion or biopsy-confirmed LSIL after ASC-US or LSIL cytology, repeat cytology is recommended at 12 mo intervals. If ASC-US or LSIL has persisted after 2 yr or if HSIL is present at any time, referral for colposcopy is recommended. In women with biopsy-confirmed LSIL after atypical squamous cells of high grade (ASC-H) or HSIL, observation with cytology and colposcopy is recommended at 6 mo intervals for up to 2 yr. For persistent ASC-H or HSIL at 2 yr or progression at any time, treatment is recommended. Any young woman with histology-confirmed HSIL can be followed by colposcopy and cytology at 6 mo intervals if the patient is compliant. If HSIL continues to persist after 2 yr of follow-up, treatment is recommended. When CIN 3 is specified, treatment is recommended. These guidelines and updates can be found at http://www.asccp.org.

Very sensitive tests for the presence of HPV DNA, RNA, and proteins are becoming generally available, although they are not required for the diagnosis of external genital warts or related conditions. There are no indications for HPV DNA testing in women younger than 21 yr of age or children. HPV DNA testing is not recommended in women 21-24 yr of age but is acceptable for ASC-US triage.

Diagnosis of juvenile laryngeal papillomatosis (JRP) is made based on laryngeal examination.

DIFFERENTIAL DIAGNOSIS

A number of other conditions should be considered in the differential diagnosis of genital warts, including condyloma lata, seborrheic keratoses, dysplastic and benign nevi, molluscum contagiosum, pearly penile papules, neoplasms, Bowen disease, Bowenoid papulosis, Buschke-Löwenstein tumors, and vulvar intraepithelial neoplasias.

Condyloma lata is caused by secondary syphilis and can be diagnosed with darkfield microscopy and standard serologic tests for syphilis. Seborrheic keratoses are common, localized, hyperpigmented lesions that are rarely associated with malignancy. Molluscum contagiosum is caused by a poxvirus, is highly infectious, and is often umbilicated. Pearly penile papules occur at the penile corona and are normal variants that require no treatment.

TREATMENT

Most common (plantar, palmar, skin) warts eventually resolve spontaneously (see Chapter 667). Symptomatic lesions should be removed. Removal includes a variety of self-applied therapies, including salicylic acid preparations and provider-applied therapies (cryotherapy, laser therapy, electrosurgery). Genital warts are benign and usually remit, but only over an extended period. It is recommended that genital lesions be treated if the patient or the parent requests therapy. Treatments for genital warts are categorized into self-applied and provider-applied. No one therapy has been shown to be more efficacious than any other. Recommended patient-applied treatment regimens for external genital warts include topical podofilox, imiquimod, and sinecatechins. Podofilox 0.5% solution (using a cotton swab) or gel (using a finger) is applied to visible warts in a cycle of applications twice a day for 3 days followed by 4 days of no therapy, repeated for up to a total of 4 cycles. Imiquimod 5% cream is applied at bedtime, 3 times a week, every other day, for up to 16 wk; the treated area should be washed with mild soap and water 6-10 hr after treatment. Sinecatechins (15% ointment) is a topical product from green tea extract used for external genital wart treatment that can be used 3 times daily for up to 16 wk. Provider-applied therapies include surgical treatments (electrosurgery, surgical excision, laser surgery) and office-based treatment (cryotherapy with liquid nitrogen or a cryoprobe, podophyllin resin 10-25%, and bichloroacetic or trichloroacetic acid). Office-based treatments are usually applied once a week for 3-6 wk. Podophyllin resins have lost favor to other methods because of the variability in preparations. Intraleisional interferon is associated with significant adverse effects and is reserved for treatment of recalcitrant cases.

Many therapies are painful, and children should not undergo painful genital treatments unless adequate pain control is provided. Parents and
patients should not be expected to apply painful therapies themselves. None of the patient-applied therapies are approved for use during pregnancy, and podophyllin resin is contraindicated in pregnancy. For any of the nonsurgical treatments, prescription is contraindicated in a patient with any history of hypersensitivity to any product constituents.

If HPV exposure as a result of sexual abuse is suspected or known, the clinician should ensure that the child's safety has been achieved and is maintained.

When indicated, the most common treatments for CIN 2/3 are ablative and excisional treatments, including cryotherapy, laser, and loop electrosurgical excisional procedures. Once confirmed by histology with CIN 1, LSILs can be observed indefinitely. The decision to treat a persistent CIN 1 rests between the provider and patient. Risks of treatment, including premature delivery in a future pregnancy, should be discussed prior to any treatment decision. Treatment in pregnancy is not recommended unless invasive cancer is present.

JRP is commonly treated with surgical removal of lesions, but laser and microdebriders are also used.

**COMPLICATIONS**
The presence of HPV lesions in the genital area may be a cause of profound embarrassment to a child or parent. Complications of therapy are uncommon; chronic pain (vulvodynia) or hypoesthesia may occur at the treatment site. Lesions may heal with hypopigmentation or hyperpigmentation and less commonly with depressed or hypertrophic scars. Surgical therapies can lead to infection and scarring. Premature delivery and low birthweight in future pregnancies are complications of excisional therapy for CIN.

It is estimated that 5-15% of untreated CIN 3 lesions will progress to cervical cancer. Most cancer is prevented by early detection and treatment of these lesions. Despite screening, cervical cancer develops rapidly in a few adolescents and young women. The reason for the rapid development of cancer in these rare cases remains unknown, but host genetic defects are likely underlying causes. Juvenile laryngeal papillomas rarely become malignant, unless they have been treated with irradiation. Vulvar condylomas rarely become cancerous. HPV-associated cancers of the vagina, vulva, anus, penis, and oral cavity are much rarer than cervical tumors, and therefore screening for them is not currently recommended. However, anal, vaginal, and vulvar cancers are more common in women with cervical cancer; hence, it is recommended to screen women with cervical cancer for these tumors with visual and/or digital inspection.

**PROGNOSIS**
With all forms of therapy, genital warts commonly recur, and approximately half of children and adolescents require a 2nd or 3rd treatment. Recurrence is also evident in patients with Juvenile laryngeal papillomatosis. Patients and parents should be warned of this likelihood.

Combination therapy for genital warts (imiquimod and podofilox) does not improve response and may increase complications. Prognosis of cervical disease is better, with 85-90% cure rates after a single treatment with the loop electrosurgical excision procedure. Cryotherapy has a slightly lower cure rate. Recalcitrant disease should prompt an evaluation and is common in immunocompromised individuals, specifically men and women infected with HIV.

**PREVENTION**
The only means of preventing HPV infection is to avoid direct contact with lesions. Condoms may reduce the risk for HPV transmission; condoms also prevent other sexually transmitted infections, which are risk factors associated with SIL development. In addition, condoms appear to hasten the regression of LSILs in women. Avoiding smoking cigarettes is important in preventing cervical cancer. Prolonged oral contraceptive use and parity have been shown to be risks for cervical cancer. However, the mechanisms associated with these factors have not been identified, and consequently no change in counseling is recommended.

HPV vaccines show efficacy against type-specific persistence and development of type-specific disease, including the cervix, vagina, vulva, and anus. A quadrivalent HPV vaccine containing types 6, 11, 16, and 18 was licensed in the United States in 2006, and a bivalent HPV vaccine containing types 16 and 18 was licensed in the United States in 2009. A 9-valent vaccine containing types 6, 11, 16, 18, 31, 33, 45, 52, and 58 has recently been approved. The efficacy of these vaccines is mediated by the development of neutralizing antibodies. Data from Sweden and Australia show a decrease in national rates of genital warts within 4 yr of implementing vaccination programs. Vaccination in the United States is recommended routinely for all girls at 11-12 yr of age and is administered intramuscularly in the deltoid region in a 3 dose series at 0, 1-2, and 6 mo. It is important that vaccination take place in children before they become sexually active, because the rate of HPV acquisition is high shortly after the onset of sexual activity. Vaccine can be given to girls as young as 9 yr of age, and a catch-up vaccination is recommended in girls 13-26 yr. Individuals who are already infected with 1 or more vaccine-related HPV types prior to vaccination are protected from clinical disease caused by the remaining vaccine HPV types. However, the vaccines are not therapeutic. The quadrivalent vaccine is also licensed to be administered in a 3 dose series to males 9 through 26 yr of age to reduce their likelihood of acquiring genital warts and developing anal dysplasia and cancer. Two doses of the vaccines have shown similar levels of immunogenicity as 3 doses. A vaccine that will cover 9 HPV high-risk types has been approved.

Chapter 267
Arboviral Infections in North America
Scott B. Halstead

The arthropod-borne viral infections in North America are a group of mosquito-transmitted pathogens of several taxa causing neurologic infections or acute viral exanthems. Neuroviruses are transmitted during warmer weather in overlapping regions across most the United States and much of southern Canada.

Etiology
The principal causes of the arthropod-borne infections (with or without encephalitis) of North America are West Nile encephalitis (WNE), St. Louis encephalitis (StLE), Powassan (POW), a complex of California encephalitis group viruses, and, less frequently, western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Colorado tick fever. Chikungunya virus is an emerging pathogen in the Western Hemisphere including the United States. The etiologic agents belong to different viral taxa: alphaviruses of the family Togaviridae (chikungunya virus, EEE, and WEE), Flaviridae (WNE, STLE, POW), the California complex of the family Bunyaviridae (California encephalitis), and Reoviridae (Colorado tick fever virus). Alphaviruses are 69 nm, enveloped, positive-sense RNA viruses that evolved from a common Venezuelan equine encephalitis-like viral ancestor in the Western Hemisphere. Flaviviruses are 40-50 nm, enveloped, positive-sense RNA viruses that evolved from a common ancestor. They are mosquito-borne (WNE, STLE) and tick-borne (POW) agents, globally distributed, and responsible for many important human viral diseases. The California serogroup, 1 of 16 Bunyavirus groups, are 75-115 nm enveloped viruses possessing a 3-segment, negative-sense RNA genome. Reoviruses are 60-80 nm double-stranded RNA viruses.

Epidemiology
Eastern Equine Encephalitis
In the United States, EEE is a very low incidence disease, with a median of 8 cases occurring annually in the Atlantic and Gulf States from 1964-2007 (Fig. 267-1). Transmission occurs often in focal endemic
water impoundments, irrigated farmland, and naturally flooded land provide breeding sites for *Culex tarsalis*. The virus is transmitted in a cycle involving mosquitoes, birds, and other vertebrate hosts. Humans and horses are susceptible to encephalitis. The case:infection ratio varies by age, having been estimated at 1:58 in children younger than 4 yr of age and 1:1,150 in adults. Infections are most severe at the extremes of life; one third of cases occur in children younger than 1 yr of age. Recurrent human epidemics have been reported from the Yakima Valley in Washington State and the Central Valley of California; the largest outbreak on record resulted in 3,400 cases and occurred in Minnesota, North and South Dakota, Nebraska, and Montana as well as Alberta, Manitoba, and Saskatchewan, Canada. Epizootics in horses precede human epidemics by several weeks. For the past 20 yr, only 3 cases of WEE have been reported, presumably reflecting successful mosquito abatement.

**Western Equine Encephalitis**

WEE infections occur principally in the United States and Canada west of the Mississippi River (see Fig. 267-1), mainly in rural areas where areas of the coast of Massachusetts, the 6 southern counties of New Jersey, and northeastern Florida. In North America, the virus is maintained in freshwater swamps in a zoonotic cycle involving *Culiseta melanura* and birds. Various other mosquito species obtain viremic meals from birds and transmit the virus to horses and humans. Virus activity varies markedly from year to year in response to still unknown ecologic factors. Most infections in birds are silent, but infections in pheasants are often fatal, and epizootics in these species are used as sentinels for periods of increased viral activity. Cases have been recognized on Caribbean islands. The case:infection ratio is lowest in children (1:8) and somewhat higher in adults (1:29).

**Figure 267-1** The distribution and incidence of reported cases of eastern equine encephalitis (A), western equine encephalitis (B), St. Louis encephalitis (C), California serogroup encephalitis (D), and Powassan encephalitis (E) reported by state to the Centers for Disease Control and Prevention, 1964–2010. (From Division of Vector-Borne Diseases, Centers for Disease Control and Prevention. Available at: [http://www.cdc.gov/ncidod/dvbid/arbor/arbocase.htm](http://www.cdc.gov/ncidod/dvbid/arbor/arbocase.htm))
St. Louis Encephalitis
Cases of STLE are reported from nearly all states; the highest attack rates occur in the Gulf and central states (see Fig. 267-1). Epidemics frequently occur in urban and suburban areas; the largest, in 1975, involved 1,800 persons living in Houston, Chicago, Memphis, and Denver. Cases often cluster in areas where there is ground water or septic systems, which support mosquito breeding. The principal vectors are Culex pipiens and Culex quinquefasciatus in the central Gulf States, Culex nigripalpus in Florida, and C. tarsalis in California. STLE virus is maintained in nature by transmission between mosquitoes of the Culex genus and various species of birds. In the United States, human infections are largely of bird–mosquito cycle. Viral amplification occurs in bird species abundant in residential areas (e.g., sparrows, blue jays, and doves). Virus is transmitted in the late summer and early fall. The case infection ratio may be as high as 1:300. Age-specific attack rates are lowest in children and highest in individuals older than age 60 yr. The most recent small outbreaks were in Florida in 1990 and Louisiana in 2001. For the past 15 yr there have been a mean of 18 cases annually.

West Nile Encephalitis
West Nile (WN) virus has been implicated as the cause of sporadic summertime cases of human encephalitis and meningitis in Israel, India, Pakistan, Romania, Russia, and the United States. All American WN viruses are genetically similar and are related to a virus recovered from a goose in Israel in 1998. WN virus was imported into the United States in 1999 and now survives in a broad enzootic cycle across the United States. Every state in the continental United States plus 9 provinces in Canada have reported mosquito, bird, mammalian, or human WN virus infection, most frequently during the summer or fall months (Fig. 267-2). Through the end of 2012, 35,941 total cases had been reported, 40-50% of which were neuroinvasive, with 1,439 deaths. WN virus transmission cycles appear to resemble those of Japanese encephalitis with large epizootics and human cases every 5-10 yr. WN virus has entered the blood supply through asymptomatic viremic potential blood donors. Blood banks screen for WN virus RNA. In 2012, 597 viremic potential blood donors were identified and the donation was rejected (Fig. 267-2). WN virus has also been transmitted to humans via the placenta, breast milk, and organ transplantation. Throughout its range, the virus is maintained in nature by transmission between mosquitoes of the Culex genus and various species of birds. In the United States, human infections are largely acquired from C. pipiens. Horses are the nonavian vertebrates most likely to exhibit disease with WN virus infection. During the 2002 transmission season, 14,000 equine cases were reported, with a mortality rate of 30%. Disease occurs predominantly in individuals >30 yr of age.

Figure 267-2 West Nile virus activity reported to ArboNET by state, United States, 2014. (Preliminary data as of October 28, 2014.) (From ArboNET, Arboviral Diseases Branch, Centers for Disease Control and Prevention. Available at: http://www.cdc.gov/westnile/statsMaps/preliminaryMapsData/activitystatedate.html)

Powassan Encephalitis
POW virus is transmitted by Ixodes cookei among small mammals in eastern Canada and the United States; it has been responsible for 39 deaths in the United States since 2008 (see Fig. 267-1). Other ticks may transmit the virus in a wider geographic area, and there is some concern that Ixodes scapularis (also called Ixodes dammini), a competent vector in the laboratory, may become involved as it becomes more prominent in the United States.

La Crosse/California Encephalitis
La Crosse viral infections are endemic in the United States, occurring annually from July to September, principally in the north-central and central states (see Fig. 267-1). Infections occur in peri-domestic environments as the result of bites from Aedes triseriatus mosquitoes, which often breed in tree holes. The virus is maintained vertically in nature by transovarial transmission and can be spread between mosquitoes by copulation and amplified in mosquito populations by viremic infections in various vertebrate hosts. Amplifying hosts include chipmunks, squirrels, foxes, and woodchucks. A case infection ratio of 1:22-300 has been surmised. La Crosse encephalitis is principally a disease of children, who may account for up to 75% of cases. A mean of 100 cases has been reported annually for the past 10 yr.

Colorado Tick Fever
Colorado tick fever virus is transmitted by the wood tick Dermacentor andersoni, which inhabits high-elevation areas of states extending from the central plains to the Pacific Coast. The tick is infected with the virus at the larval stage and remains infected for life. Squirrels and chipmunks serve as primary reservoirs. Human infections typically occur in hikers and campers in indigenous areas during the spring and early summer.

Chikungunya Virus
Chikungunya virus is endemic in Africa and Asia as well as parts of Latin America. It is an emerging pathogen in areas of the United States inhabited by day biting mosquitoes (Aedes aegyti, Aedes albopictus).

CLINICAL MANIFESTATIONS
The arboviruses produce symptoms of viral meningitis or encephalitis. WN virus and Colorado tick fever illnesses more commonly manifest as flulike diseases and only occasionally as encephalitides.

Eastern Equine Encephalitis
EEE virus infections result in fulminant encephalitis with a rapid progression to coma and death in one third of cases. In infants and children, abrupt onset of fever, irritability, and headache are followed by lethargy, confusion, seizures, and coma. High temperature, bulging fontanel, stiff neck, and generalized flaccid or spastic paralysis are observed. There may be a brief prodrome of fever, headache, and dizziness. Unlike most other viral encephalitides, the peripheral white blood cell count usually demonstrates a marked leukocytosis, and the cerebrospinal fluid (CSF) may show marked pleocytosis. Pathologic changes are found in the cortical and gray matter, with viral antigens localized to neurons. There is necrosis of neurons, neutrophilic infiltration, and perivascular cuffing by lymphocytes.

Western Equine Encephalitis
In WEE, there may be a prodrome with symptoms of an upper respiratory tract infection. The onset is usually sudden with chills, fever, dizziness, drowsiness, increasing headache, malaise, nausea and vomiting, stiff neck, and disorientation. Infants typically present with the sudden cessation of feeding, fussiness, fever, and protracted vomiting. Convulsions and lethargy develop rapidly. On physical examination, patients are somnolent, exhibit meningeal signs, and have generalized motor weakness and reduced deep tendon reflexes. In infants, a bulging fontanel, spastic paralysis, and generalized convulsions may be observed. On pathologic examination, disseminated small focal abscesses, small focal hemorrhages, and patchy areas of demyelination are distinctive.

**St. Louis Encephalitis**
Clinical manifestations of STLE vary from a mild febrile illness to fatal encephalitis. There may be a prodrome of nonspecific symptoms with subtle changes in coordination or mentation of several days to 1 wk in duration. Early signs and symptoms include fever, photophobia, headache, malaise, nausea, vomiting, and neck stiffness. About half of patients exhibit abrupt onset of weakness, incoordination, disturbed sensorium, restlessness, confusion, lethargy, and delirium or coma. The peripheral white blood cell count is modestly elevated, with 100-200 cells/µL found in the CSF. On autopsy, the brain shows scattered foci of neuronal damage and perivascular inflammation.

**West Nile Encephalitis**
WNE may be asymptomatic, but when clinical features appear, they include an abrupt onset of high fever, headache, myalgias, and non-specific signs of emesis, rash, abdominal pain, or diarrhea. Most infections manifest as a flulike febrile illness, whereas a minority of patients develop meningoencephalitis or encephalitis, or both. Rarely there may be cardiac dysrhythmias, myocarditis, rhabdomyolysis, optic neuritis, uveitis, retinitis, orchitis, pancreatitis, or hepatitis. WN virus disease in the United States has been accompanied by prolonged lymphopenia and an acute asymmetric polylike paralytic illness with CSF pleocytosis involving the anterior horn cells of the spinal cord. A striking but uncommon feature has been parkinsonism and movement disorders (with tremor and myoclonus). WN virus infections have been shown to lead to chronic kidney disease in a small group of patients.

**Powassan Encephalitis**
POW encephalitis has occurred mostly in adults living in enzootic areas with vocational or recreational exposure; it is associated with significant long-term morbidity and has a case-fatality rate of 10-15%.

**Lacrosse/California Encephalitis**
The clinical spectrum includes a mild febrile illness, aseptic meningitis, and fatal encephalitis. Children typically present with a prodrome of 2-3 days with fever, headache, malaise, and vomiting. The disease evolves with clouding of the sensorium, lethargy, and, in severe cases, focal or generalized seizures. On physical examination, children are lethargic but not disoriented. Focal neurologic signs, including weakness, aphasia, and focal or generalized seizures, have been reported in 16-25% of cases. CSF shows low to moderate leukocyte counts. On autopsy, the brain shows focal areas of neuronal degeneration, inflammation, and perivascular cuffing.

**Colorado Tick Fever**
Colorado tick fever begins with the abrupt onset of a flulike illness, including high temperature, malaise, arthralgia and myalgia, vomiting, headache, and decreased sensorium. Rash is uncommon. The symptoms rapidly disappear after 3 days of illness. However, in approximately half of patients, a second identical episode reoccurs 24-72 hr after the first, producing the typical “saddleback” temperature curve of Colorado tick fever. Complications, including encephalitis, meningoencephalitis, and a bleeding diathesis, develop in 3-7% of infected persons and may be more common in children younger than 12 yr of age.

**Chikungunya Virus**
Clinical manifestations begin 3-7 days after a mosquito bite and begin abruptly with high fever and severe joint symptoms (hands, feet, ankles, wrists) that include symmetric bilateral polyarthralgia or arthritis. Most patients are symptomatic, and all ages are vulnerable. In addition, there may be headache, myalgias, conjunctivitis, weakness, lymphopenia, and a maculopapular rash. Mortality is rare; some develop prolonged joint symptoms (tenosynovitis, arthritis) lasting over a year. The acute episode lasts 7-10 days. The differential diagnosis includes dengue, West Nile, enterovirus diseases, leptospirosis, rickettsial disease, measles, parvovirus disease, rheumatologic diseases, and other alphavirus diseases in endemic areas. Figure 267-3 lists the diagnostic criteria.

**DIAGNOSIS**
The etiologic diagnosis of a specific arboviral infection is established by testing an acute-phase serum ≥5 days after onset of illness for the presence of virus-specific immunoglobulin (Ig) M antibodies using an indirect immunofluorescence test or an enzyme-linked immunosorbent assay IgM capture test. Alternatively, acute and convalescent sera can be tested for a 4-fold or greater increase in enzyme-linked immunosorbent assay, hemagglutination inhibition, or neutralizing IgG antibody titers. Commercial serologic diagnostic kits are marketed, especially for WN viral infections. Serum and CSF should be tested for WN virus–specific IgM. However, IgM may reflect past infection, because it may be present up to 12 mo after infection. The diagnosis may also be established by isolation in cell cultures of virus in brain tissue, obtained by brain biopsy or at autopsy, or by identification of viral RNA reverse transcriptase polymerase chain reactions.

The diagnosis of encephalitis may be aided by CT or MRI and by electroencephalography. Focal seizures or focal findings on CT or MRI or electroencephalography should suggest the possibility of herpes simplex encephalitis, which should be treated with acyclovir (see Chapter 252).

![Figure 267-3 Diagnostic criteria for chikungunya virus fever.](From Burt FJ, Rolph MS, Rulli NE, et al: Chikungunya: a re-emerging virus, Lancet 379:662–668, 2012, Fig. 6.)
TREATMENT
There is no specific treatment for arboviral encephalitides, although oral ribavirin may have been of benefit in a case of La Crosse encephalitis. The treatment of acute arboviral encephalitis is intensive supportive care (see Chapter 67), including control of seizures (see Chapter 593).

PROGNOSIS
Fatalities occur with all arboviral encephalitides. With the exception of EEE, most resolve without residua.

Eastern Equine Encephalitis
The prognosis in EEE is better for patients with a prolonged prodrome; the occurrence of convulsions conveys a poor prognosis. Patient fatality rates are 33-75% and are highest in the elderly. Residual neurologic defects are common, especially in children.

Western Equine Encephalitis
Patient fatality rates in WEE are 3-9% and highest in the elderly. Major neurologic sequelae have been reported in up to 13% of cases and may be as high as 30% in infants. Parkinsonian syndrome has been reported as a residual in adult survivors.

St. Louis Encephalitis
The principal risk factor for fatal outcome of STLE is advanced age, with patient fatality rates being as high as 80% in early outbreaks. In children, mortality rates are 2-5%. In adults, underlying hypertensive cardiovascular disease has been a risk factor for fatal outcome. Recovery from STLE is usually complete, but the rate of serious neurologic sequelae has been reported to be as high as 10% in children.

West Nile Encephalitis
Cases and deaths caused by WNE occur mainly in the elderly, although many serologic surveys show that persons of all ages are infected. In 2012, among a total of 5,387 human cases, 2,734 were neuroinvasive disease, which resulted in 243 deaths, an 8.9% mortality rate (Fig. 267-4). Paralysis may result in permanent weakness.

Powassan Encephalitis
In a limited experience, POW encephalitis has occurred mainly in adults with vocational or recreational exposure and has a high fatality rate.

La Crosse or California Encephalitis
Recovery from California encephalitis is usually complete. The case fatality rate is approximately 1%.

Colorado Tick Fever
Recovery from Colorado tick fever is usually complete. Three deaths have been reported, all in persons with hemorrhagic signs.

Chikungunya
The incidence of febrile convulsions is high in infants. Prognosis is generally good, although in large outbreaks in Africa and India severe disease and deaths have been attributed to chikungunya infections, predominantly in adults.

PREVENTION
Killed EEE, WEE, and WNE vaccines are available for horses, and an experimental killed vaccine is administered to human laboratory workers who handle EEE virus. Flocks of sentinel chickens or pheasants have been stationed at various locations along the Atlantic coast during the late summer or early fall to obtain early warning of increased transmission of EEE virus. No human vaccine is licensed for arboviral encephalitides, although several WNE vaccines are in late-stage development. Killed WNE vaccines are licensed for veterinary use. Protection against CHIK is attained by avoiding bites by vector mosquitoes. These bite during daytime hours in and around human habitations (see Chapter 269).

Extensive water management and mosquito abatement programs in California have reduced transmission of WEE and the incidence of human infections. Urban WNE and STLE outbreaks in the eastern United States, Texas, and the Midwest have been controlled by the application of ultra-low-volume adulticide chemicals applied from trucks or low-flying aircraft. Because mosquito biting may occur in and around residential areas, sealing mosquito breeding sites, using insect repellents, and instructing children to play in open, sunny areas away from forest fringe may help prevent disease.

Because there is no vaccine or specific therapy for POW encephalitis, the best means of prevention is protection from tick bite. This includes using insect repellents, wearing light-colored clothing with long sleeves and pants tucked into socks or boots, avoiding or clearing brushy areas, and removing ticks before they attach or soon after attachment. Checking family pets also can prevent ticks from entering the home. Because *I. cookei* are often found on woodchucks and skunks and may be the primary vector of POW virus, reducing human contact with small and medium-sized mammals may reduce risk of exposure to POW virus-infected ticks. Areas around homes in enzootic areas should be kept clear of brush, weeds, trash, and other elements that could support small and medium-sized mammals. When removing rodent nests, avoid direct contact with nesting materials and use sealed plastic bags for disposal and to prevent direct contact with ticks.

Bibliography
Globally, the principal causes of arboviral encephalitis are Venezuelan equine encephalitis (VEE), Japanese encephalitis (JE), West Nile fever (WN), and tickborne encephalitis (TBE) (Table 268-1). Other widespread arboviral infections include chikungunya (CHIK) and dengue (DEN) (see Chapter 269).
268.1 Venezuelan Equine Encephalitis

The VEE virus was isolated from an epizootic in Venezuelan horses in 1938. Human cases were first identified in 1943. Hundreds of thousands of equine and human cases have occurred over the past 70 yr. During 1971, epizootics moved through Central America and Mexico to southern Texas. After 2 decades of quiescence, epizootic disease emerged again in Venezuela and Colombia in 1995.

ETIOLOGY

VEE is an alphavirus of the family Togaviridae. VEE circulates in nature in 6 subtypes. Virus types I and III have multiple antigenic variants. Types IAB and IC have caused epizootics and human epidemics.

EPIDEMIOLOGY

The majority of epizootics resulting from types IAB and IC have occurred in Venezuela and Colombia. The virus resides in ill-defined sylvatic reservoirs in the South American rain forests. Known hosts include rodents and aquatic birds with transmission by *Culex melanoconion* species. Vectors for horse-to-horse and horse-to-human transmission include *Aedes taeniorhynchus* and *Psorophora confluens*. Epizootics move rapidly, up to several miles per day. Human cases are proportional to and follow epizootic occurrences. Viremia levels in human blood are high enough to infect mosquitoes. Because virus can be recovered from human pharyngeal swabs, and household attack rates are often as high as 50%, it is widely believed that person-to-person transmission occurs, although direct evidence is lacking. Virus types II-VI are restricted to relatively small foci; each has a unique vector–host relationship and rarely results in human infections.

CLINICAL MANIFESTATIONS

The incubation period is 2-5 days, followed by the abrupt onset of fever, chills, headache, sore throat, myalgia, malaise, prostration, photophobia, nausea, vomiting, and diarrhea. In 5-10% of cases, there is a biphasic illness; the 2nd phase is heralded by seizures, projectile vomiting, ataxia, confusion, agitation, and mild disturbances in consciousness. There is cerebral lymphadenopathy and conjunctival suffusion. Cases of meningoencephalitis may demonstrate cranial nerve palsy, motor weakness, paralysis, seizures, and coma. Microscopic examination of tissues reveals inflammatory infiltrates in lymph nodes, spleen, lung, liver, and brain. Lymph nodes show cellular depletion, necrosis of germinal centers, and lymphphagocytosis. The liver shows patchy hepatocellular degeneration, the lungs demonstrate a diffuse interstitial pneumonia with intraalveolar hemorrhages, and the brain shows patchy cellular infiltrates.

DIAGNOSIS

The etiologic diagnosis of VEE is established by testing an acute-phase serum collected early in the illness for the presence of virus-specific immunoglobulin (Ig) M antibodies or, alternatively, demonstrating a 4-fold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by isolation in tissue cultures or recovery of viral RNA by polymerase chain reaction.

TREATMENT

There is no specific treatment for VEE. The treatment is intensive supportive care (see Chapter 67), including control of seizures (see Chapter 593).

PROGNOSIS

In patients with VEE meningoencephalitis, the fatality rate ranges from 10-25%. Sequelae include nervousness, forgetfulness, recurrent headache, and easy fatigability.

PREVENTION

Several veterinary vaccines are available to protect equines. VEE virus is highly infectious in laboratory settings, and biosafety level 3 containment should be used. An experimental vaccine is available for use in laboratory workers. Several vaccine constructs are in the pipeline for potential use in humans.

268.2 Japanese Encephalitis

Scott B. Halstead

Epidemics of encephalitis were reported in Japan from the late 1800s.

ETIOLOGY

JE virus is a positive-sense, single-stranded RNA virus of the family Flaviviridae.

EPIDEMIOLOGY

JE is a mosquito-borne viral disease of humans as well as horses, swine, and other domestic animals that causes human infections and acute disease in a vast area of Asia, northern Japan, Korea, China, Taiwan, the Philippines, and the Indonesian archipelago and from Indochina through the Indian subcontinent. *Culex tritaeniorhynchus summatorius*, a nightbiting mosquito that feeds preferentially on large domestic animals and birds but only infrequently on humans, is the principal vector of zoonotic disease in a vast area of Asia, northern Japan, Korea, China, Taiwan, the Philippines, and the Indonesian archipelago and from Indochina through the Indian subcontinent. *Culex vishnui* group are vectors. Before the introduction of JE vaccine, summer outbreaks of JE occurred regularly in Japan, Korea, China, Okinawa, and Taiwan. Over the past decade, there has been a pattern of steadily enlarging recurrent seasonal outbreaks in Vietnam, Thailand, Nepal, and India, with small outbreaks in the Philippines, Indonesia, and the northern tip of Queensland, Australia. Seasonal rains are accompanied by increases in mosquito populations and JE transmission. Pigs serve as an amplifying host.

The annual incidence in endemic areas ranges from 1-10 per 10,000 population. Children younger than 15 yr of age are principally affected, with nearly universal exposure by adulthood. The case:infection ratio for JE virus has been variously estimated at 1:25 to 1:1,000. Higher ratios have been estimated for populations indigenous to enzootic areas. JE occurs in travelers visiting Asia; therefore, a travel history in the diagnosis of encephalitis is critical.
Bibliography
CLINICAL MANIFESTATIONS
After a 4-14 day incubation period, cases typically progress through the following 4 stages: prodromal illness (2-3 days), acute stage (3-4 days), subacute stage (7-10 days), and convalescence (4-7 wk). Onset may be characterized by abrupt onset of fever, headache, respiratory symptoms, anorexia, nausea, abdominal pain, vomiting, and sensory changes, including psychotic episodes. Grand mal seizures are seen in 10-24% of children with JE; parkinsonian-like nonintention tremor and cogwheel rigidity are seen less frequently. Particularly characteristic are rapidly changing central nervous system signs (e.g., hyperreflexia followed by hyporeflexia or plantar responses that change). The sensory status of the patient may vary from confusion through disorientation and delirium to somnolence, progressing to coma. There is usually a mild pleocytosis (100-1,000 leukocytes/µL) in the cerebrospinal fluid, initially polymorphonuclear but in a few days predominantly lymphocytic. Albuminuria is common. Fatal cases usually progress rapidly to coma, and the patient dies within 10 days.

DIAGNOSIS
JE should be suspected in patients reporting exposure to night-biting mosquitoes in endemic areas during the transmission season. The etiologic diagnosis of JE is established by testing acute-phase serum collected early in the illness for the presence of virus-specific IgM antibodies or, alternatively, demonstrating a fourfold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by polymerase chain reaction.

TREATMENT
There is no specific treatment for JE. The treatment is intensive supportive care (see Chapter 67), including control of seizures (see Chapter 593).

PROGNOSIS
Patient fatality rates for JE are 24-42% and are highest in children 5-9 yr of age and in adults older than 65 yr of age. The frequency of sequelae is 5-70% and is directly related to the age of the patient and severity of disease. Sequelae are most common in patients younger than 10 yr at the onset of disease. The more common sequelae are mental deterioration, severe emotional instability, personality changes, motor abnormalities, and speech disturbances.

PREVENTION
Travelers to endemic countries who plan to be in rural areas of the endemic region during the expected period of seasonal transmission and travelers in rural areas experiencing endemic transmission should receive JE vaccine. An inactivated vaccine manufactured in Japan by intracerebral injection of young mice and available throughout the world has been taken off the market owing to a high incidence of adverse events. In 2008-2009, tissue culture–based JE vaccine (Ixiaro) was licensed in Europe, Australia, and the United States. In the United States, this vaccine (also called IC51) is licensed for use in children and adults and is distributed by Novartis (Basel). For this vaccine, JE virus is grown in Vero cells, then formalin inactivated and administered intramuscularly as 2 doses of 0.5 mL each, 28 days apart. The final dose should be completed at least 1 wk prior to the patient’s expected arrival in a JE endemic area. This vaccine contains alum and protamine sulfate and has exhibited only mild adverse events. A highly efficacious live-attenuated single-dose JE vaccine developed in China for children is licensed and marketed in some Asian countries. This vaccine can be coadministered with live-attenuated measles vaccine without altering the immune responses to either vaccine. In humans, prior dengue virus infection provides partial protection from clinical JE.

Personal measures should be taken to reduce exposure to mosquito bites, especially for short-term residents in endemic areas. They consist of avoiding evening outdoor exposure, using insect repellents, covering the body with clothing, and using bed nets or house screening.

Insecticides may be applied from portable sprayers or from helicopters or light aircraft.

Bibliography is available at Expert Consult.

268.3 Tickborne Encephalitis
Scott B. Halstead

TBE is widespread in Europe, where it has also been identified as the cause of milkborne encephalitis.

ETIOLOGY
TBE virus is a positive-sense, single-stranded RNA virus of the family Flaviviridae.

EPIDEMIOLOGY
TBE refers to neurotropic tick-transmitted flaviviral infections occurring across the Eurasian land mass. In the Far East, the disease is called Russian spring-summer encephalitis; the milder, often biphasic form in Europe is simply called TBE. TBE is found in all countries of Europe except Portugal and the Benelux countries. The incidence is particularly high in Austria, Poland, Hungary, Czech Republic, Slovakia, former Yugoslavia, and Russia. The incidence tends to be very focal. Seroprevalence is as high as 50% in farm and forestry workers. The majority of cases occur in adults, but even young children may be infected while playing in the woods or on picnics or camping trips. The seasonal distribution of cases is midsummer in southern Europe, with a longer season in Scandinavia and the Russian Far East. TBE can be excreted from the milk of goats, sheep, or cows. Before World War II, when milk was consumed unpasteurized, milkborne cases of TBE were common.

Viruses are transmitted principally by hard ticks of Ixodes ricinus in Europe and Ixodes persulcatus in the Far East. Viral circulation is maintained by a combination of transmission from ticks to birds, rodents, and larger mammals and transtadial transmission from larval to nymphal and adult stages. In some parts of Europe and Russia, ticks feed actively during the spring and early fall, giving rise to the name “spring-summer encephalitis.”

CLINICAL MANIFESTATIONS
After an incubation period of 7-14 days, the European form begins as an acute nonspecific febrile illness that is followed in 5-30% of cases by meningoencephalitis. The Far Eastern variety more often results in encephalitis with higher case fatality and sequelae rates. The 1st phase of illness is characterized by fever, headache, myalgia, malaise, nausea, and vomiting for 2-7 days. Fever disappears and after 2-8 days may return accompanied by vomiting, photophobia, and signs of meningeal irritation in children and more severe encephalitic signs in adults. This phase rarely lasts more than 1 wk.

DIAGNOSIS
The diagnosis of TBE should be suspected in any patient reporting a tick bite in an endemic area during the transmission season. The etiologic diagnosis of TBE is established by testing acute-phase serum collected early in the illness for the presence of virus-specific IgM antibodies or, alternatively, demonstrating a 4-fold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by polymerase chain reaction. With widespread use of vaccines, an IgM titer of >500 arbitrary units in early convalescent serum has been recommended for the diagnosis of acute TBE.

TREATMENT
There is no specific treatment for TBE. The treatment is intensive supportive care (see Chapter 67), including control of seizures (see Chapter 593).

PROGNOSIS
The main risk for fatal outcome is advanced age; the fatality rate in adults is approximately 1%, but sequelae in children are rare. Transient...
unilateral paralysis of an upper extremity is a common finding in adults. Common sequelae include chronic fatigue, headache, sleep disorders, and emotional disturbances.

**PREVENTION**
Specific immunoglobulin has been given to persons with seasonal tick bite exposure, although efficacy of this preventive therapy is not well studied. Effective inactivated vaccines for human use, made from virus grown in tissue culture, are licensed in Russia and Europe. They are administered in a 3 dose series.

*Bibliography is available at Expert Consult.*

**268.4 West Nile Encephalitis**
See Chapter 267.
Bibliography

Dengue fever is a benign syndrome caused by several arthropod-borne viruses and is characterized by biphasic fever, myalgia or arthralgia, rash, leukopenia, and lymphadenopathy. Dengue hemorrhagic fever (Philippine, Thai, or Singapore hemorrhagic fever; hemorrhagic dengue; acute infectious thrombocytopenic purpura) is a severe, often fatal, febrile disease caused by 1 of 4 dengue viruses. It is characterized by capillary permeability, abnormalities of hemostasis, and, in severe cases, a protein-losing shock syndrome (dengue shock syndrome), which is thought to have an immunopathologic basis.

**ETIOLOGY**

There are at least 4 distinct antigenic types of dengue virus (dengue 1, 2, 3, and 4), members of the family Flaviviridae. In addition, 3 other arthropod-borne viruses (arboviruses) cause similar or identical febrile diseases with rash (Table 269-1).

**EPIDEMIOLOGY**

Dengue viruses are transmitted by mosquitoes of the Stegomyia family. *Aedes aegypti*, a daytime biting mosquito, is the principal vector, and all 4 virus types have been recovered from it. In most tropical areas, *A. aegypti* is highly urbanized, breeding in water stored for drinking or bathing and in rainwater collected in any container. Dengue viruses have also been recovered from *Aedes albopictus*, as in the 2001 Hawaiian epidemic, whereas outbreaks in the Pacific area have been attributed to several other *Aedes* species. These species breed in water trapped in vegetation. In Southeast Asia and West Africa, dengue virus may be maintained in a cycle involving canopy-feeding jungle monkeys and *Aedes* species, which feed on monkeys.

Epidemics were common in temperate areas of the Americas, Europe, Australia, and Asia until early in the 20th century. Dengue fever and dengue-like disease are now endemic in tropical Asia, the South Pacific Islands, northern Australia, tropical Africa, the Arabian Peninsula, the Caribbean, and Central and South America. Dengue fever occurs frequently among travelers to these areas. Locally acquired disease has been reported in Florida and Texas, and imported cases in the United States occur in travelers to endemic areas. More than 390 million dengue infections occur annually; approximately 96 million have clinical disease.

Dengue outbreaks in urban areas infested with *A. aegypti* may be explosive; up to 70-80% of the population may be involved. Most overt disease occurs in older children and adults. Because *A. aegypti* has a limited flight range, spread of an epidemic occurs mainly through viremic human beings and follows the main lines of transportation. Sentinel cases may infect household mosquitoes; a large number of nearly simultaneous secondary infections give the appearance of a contagious disease. Where dengue is endemic, children and susceptible foreigners may be the only persons to acquire overt disease, as adults have become immune.

**Dengue-Like Diseases**

Dengue-like diseases may occur in epidemics. Epidemiologic features depend on the vectors and their geographic distribution (see Table 269-1). Chikungunya virus is enzootic throughout much of West, Central, and South Africa as well as Central America and recently the southern United States. Periodic introductions of virus into the urban transmission cycle have led to pandemics, resulting in widespread endemicity in the most populous areas of Asia. In Asia, *A. aegypti* is the principal vector; in Africa, other Stegomyia species may be important vectors. In Southeast Asia, dengue and chikungunya outbreaks occur concurrently. Outbreaks of o’nyong-nyong fever usually involve villages or small towns, in contrast to the urban outbreaks of dengue and chikungunya. West Nile virus is enzootic in Africa. Chikungunya is now endemic in urban cycles in tropical countries throughout the world. Intense transmission in Caribbean countries presages emergence of chikungunya into the United States.

**Dengue Hemorrhagic Fever**

Dengue hemorrhagic fever occurs where multiple types of dengue virus are simultaneously or sequentially transmitted. It is endemic in all of tropical America and Asia, where warm temperatures and the practices of water storage in homes plus outdoor breeding sites result in large, permanent populations of *A. aegypti*. Under these conditions, infections with dengue viruses of all types are common. A first infection, referred to as a primary infection, may be followed by infection with a different dengue virus, referred to as a secondary infection. In areas of high endemicity secondary infections are frequent.

Secondary dengue infections are relatively mild in the majority of instances, ranging from an inapparent infection through an undifferentiated upper respiratory tract or dengue-like disease, but may also progress to dengue hemorrhagic fever. Nonimmune foreigners, both adults and children, who are exposed to dengue virus during outbreaks of hemorrhagic fever have classic dengue fever or even milder disease. The differences in clinical manifestations of dengue infections between natives and foreigners in Southeast Asia are related more to immunologic status than to racial susceptibility. Dengue hemorrhagic fever can occur during primary dengue infections, most frequently in infants whose mothers are immune to dengue. Dengue hemorrhagic fever or severe dengue occurs rarely in individuals of African ancestry because of an as yet

undiagnosed resistance gene that would explain the low incidence of severe dengue throughout much of Africa and among African populations in the American tropics despite high rates of dengue infection.

**PATHOGENESIS**

Fatalities with chikungunya and West Nile fever infections are not common but have been ascribed to viral encephalitis.

The pathogenesis of dengue hemorrhagic fever is incompletely understood, but epidemiologic studies suggest that it is usually associated with second heterotypic infections with dengue types 1-4. Retroviral studies of sera from human mothers whose infants acquired dengue hemorrhagic fever and prospective studies in children acquiring sequential dengue infections have shown that the circulation of infection-enhancing antibodies at the time of infection is the strongest risk factor for development of severe disease. Absence of cross-reactive neutralizing antibodies and presence of enhancing antibodies from passive transfer or active production are the best correlates of risk for dengue hemorrhagic fever. Monkeys that are infected sequentially or are receiving small quantities of enhancing antibodies have enhanced viremias. In humans studied early during the course of secondary dengue infections, viremia levels directly predicted disease severity. When dengue virus immune complexes attach to macrophage Fc receptors, a signal is sent that suppresses innate immunity, resulting in enhanced viral production. In the Americas, dengue hemorrhagic fever and dengue shock syndrome have been associated with dengue types 1-4 strains of recent Southeast Asian origin. Recent occurrences of sizable dengue hemorrhagic fever outbreaks in India, Pakistan, and Bangladesh also appear to be related to imported dengue strains.

Early in the acute stage of secondary dengue infections, there is rapid activation of the complement system. Shortly before or during shock, blood levels of soluble tumor necrosis factor receptor, interferon-γ, and interleukin-2 are elevated. C1q, C3, C4, C5-C8, and C3 proactivators are depressed, and C3 catalytic rates are elevated. These factors, the virus itself, or viral nonstructural protein 1 (NS1) may interact with endothelial cells, blood clotting factors, and platelets to produce increased vascular permeability. The blood clotting and fibrinolytic systems are activated, and levels of factor XII (Hageman factor) are depressed. The mechanism of bleeding in dengue hemorrhagic fever is not known, but a mild degree of disseminated intravascular coagulopathy, liver damage, and thrombocytopenia may operate synergistically. Capillary damage allows fluid, electrolytes, small proteins, and, in some instances, red blood cells to leak into extravascular spaces. This internal redistribution of fluid, together with deficits caused by fasting, thirsting, and vomiting, results in hemococoncentration, hypovolemia, increased cardiac work, tissue hypoxia, metabolic acidosis, and hyponatremia.

Usually no pathologic lesions are found to account for death. In rare instances, death may be a result of gastrointestinal or intracranial hemorrhages. Minimal to moderate hemorrhages are seen in the upper gastrointestinal tract, and petechial hemorrhages are common in the interventricular septum of the heart, on the pericardium, and on the suberosal surfaces of major viscera. Focal hemorrhages are occasionally seen in the lungs, liver, adrenals, and subarachnoid space. The liver is usually enlarged, often with fatty changes. Yellow, watery, and at times blood-tined effusions are present in serous cavities in approximately 75% of patients at autopsy.

Dengue virus is frequently absent in tissues at the time of death; viral antigens or RNA have been localized to hepatocytes and macrophages in liver, spleen, lung, and lymphatic tissues.

**CLINICAL MANIFESTATIONS**

**Dengue Fever**

The incubation period is 1-7 days. The clinical manifestations are variable and are influenced by the age of the patient. In infants and young children, the disease may be undifferentiated or characterized by fever for 1-5 days, pharyngeal inflammation, rhiinitis, and mild cough. A majority of infected older children and adults experience sudden onset of fever, with temperature rapidly increasing to 39.4-41.1°C (103-106°F), usually accompanied by frontal or retroorbital pain, particularly when pressure is applied to the eyes. Occasionally, severe back pain precedes the fever (back-break fever). A transient, macular, generalized rash that blanches under pressure may be seen during the 1st 24-48 hr of fever. The pulse rate may be slow relative to the degree of fever. Myalgia and arthralgia occur soon after the onset of fevers and increase in severity over time. Joint symptoms may be particularly severe in patients with chikungunya or o’nyong-nyong infection. From the 2nd-6th day of fever, nausea and vomiting are apt to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgiesia, taste aberrations, and pronounced anorexia may develop.

Approximately 1-2 days after defervescence, a generalized, morbilliform, maculopapular rash appears that spares the palms and soles. It disappears in 1-5 days; desquamation may occur. Rarely there is edema of the palms and soles. About the time this second rash appears, the body temperature, which has previously decreased to normal, may become slightly elevated and demonstrate the characteristic biphasic temperature pattern.

**Dengue Hemorrhagic Fever**

Differentiation between dengue fever and dengue hemorrhagic fever is difficult early in the course of illness. A relatively mild 1st phase with abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough may be followed after 2-5 days by rapid clinical deterioration and collapse. In this 2nd phase, the patient usually has cold, clammy extremities, a warm trunk, flushed face, diaphoresis, restlessness, irritability, midepigastic pain, and decreased urinary output. Frequently, there are scattered petechiae on the forehead and extremities; spontaneous ecchymoses may appear, and easy bruising and bleeding at sites of venipuncture are common. A macular or maculopapular rash may appear, and there may be circulatory and peripheral cyanosis. Respirations are rapid and often labored. The pulse is weak, rapid, and thready, and the heart sounds are faint. The liver may enlarge to 4-6 cm below the costal margin and is usually firm and somewhat tender. Approximately 20-30% of cases of dengue hemorrhagic fever are complicated by shock (dengue shock syndrome). Dengue shock can be subtle, arising in patients who are fully alert, and is accompanied by increased peripheral vascular resistance and raised diastolic blood pressure. Shock is not from congestive heart failure but from venous pooling. With increasing cardiovascular compromise, diastolic pressure rises toward the systolic level and the pulse pressure narrows. Fewer than 10% of patients have gross ecchymosis or gastrointestinal bleeding, usually after a period of uncorrected shock. After a 24-36 hr period of crisis, convalescence is fairly rapid in the children who recover. The temperature may return to normal before or during the stage of shock. Bradycardia and ventricular extrasystoles are common during convalescence.

**DIAGNOSIS**

A clinical diagnosis of dengue fever derives from a high index of suspicion and knowledge of the geographic distribution and environmental cycles of causal viruses. Because clinical findings vary and there are many possible causative agents, the term dengue-like disease should be used until a specific diagnosis is established. A case is confirmed by isolation of the virus, viral antigen, or genome by polymerase chain reaction analysis, as well as demonstration of a 4-fold or greater increase in severity over time. Joint symptoms may be particularly severe in patients with chikungunya or o’nyong-nyong infection. From the 2nd-6th day of fever, nausea and vomiting are apt to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgiesia, taste aberrations, and pronounced anorexia may develop.

Approximately 1-2 days after defervescence, a generalized, morbilliform, maculopapular rash appears that spares the palms and soles. It disappears in 1-5 days; desquamation may occur. Rarely there is edema of the palms and soles. About the time this second rash appears, the body temperature, which has previously decreased to normal, may become slightly elevated and demonstrate the characteristic biphasic temperature pattern.

**Dengue Hemorrhagic Fever**

Differentiation between dengue fever and dengue hemorrhagic fever is difficult early in the course of illness. A relatively mild 1st phase with abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough may be followed after 2-5 days by rapid clinical deterioration and collapse. In this 2nd phase, the patient usually has cold, clammy extremities, a warm trunk, flushed face, diaphoresis, restlessness, irritability, midepigastic pain, and decreased urinary output. Frequently, there are scattered petechiae on the forehead and extremities; spontaneous ecchymoses may appear, and easy bruising and bleeding at sites of venipuncture are common. A macular or maculopapular rash may appear, and there may be circulatory and peripheral cyanosis. Respirations are rapid and often labored. The pulse is weak, rapid, and thready, and the heart sounds are faint. The liver may enlarge to 4-6 cm below the costal margin and is usually firm and somewhat tender. Approximately 20-30% of cases of dengue hemorrhagic fever are complicated by shock (dengue shock syndrome). Dengue shock can be subtle, arising in patients who are fully alert, and is accompanied by increased peripheral vascular resistance and raised diastolic blood pressure. Shock is not from congestive heart failure but from venous pooling. With increasing cardiovascular compromise, diastolic pressure rises toward the systolic level and the pulse pressure narrows. Fewer than 10% of patients have gross ecchymosis or gastrointestinal bleeding, usually after a period of uncorrected shock. After a 24-36 hr period of crisis, convalescence is fairly rapid in the children who recover. The temperature may return to normal before or during the stage of shock. Bradycardia and ventricular extrasystoles are common during convalescence.

**DIAGNOSIS**

A clinical diagnosis of dengue fever derives from a high index of suspicion and knowledge of the geographic distribution and environmental cycles of causal viruses. Because clinical findings vary and there are many possible causative agents, the term dengue-like disease should be used until a specific diagnosis is established. A case is confirmed by isolation of the virus, viral antigen, or genome by polymerase chain reaction analysis, as well as demonstration of a 4-fold or greater increase in antibody titers. A probable case is a typical acute febrile illness with supportive serology and occurrence at a location where there are confirmed cases.

The World Health Organization criteria for dengue hemorrhagic fever are fever (2-7 days in duration or biphasic), minor or major hemorrhagic manifestations, thrombocytopenia (≤100,000/µL), and objective evidence of increased capillary permeability (hematocrit increased by ≥20%), pleural effusion or ascites (by chest radiography or ultrasonography), or hypoalbuminemia. Dengue shock syndrome criteria include those for dengue hemorrhagic fever as well as hypotension, tachycardia, narrow pulse pressure (≤20 mm Hg), and signs of poor perfusion (cold extremities).

In 2009, the World Health Organization promulgated new guidelines for the diagnosis of probable dengue, dengue with warning signs, and a category called “severe dengue.” Occurrence of warning signs in an individual with probable dengue should alert the physician to the need for hospitalization. Severe dengue is a mixture of syndromes associated
with dengue infection. This includes classical dengue hemorrhagic fever and dengue shock syndrome, but also rare instances of encephalitis or encephalopathy associated with dengue infection. Severe dengue also includes respiratory distress that may be a harbinger of pulmonary edema caused by overhydration, an all too common outcome of inexpert treatment (see “Treatment” and “Complications” sections).

Virologic diagnosis can be established by serologic tests, by detection of viral proteins or viral RNA, or by the isolation of the virus from blood leukocytes or acute-phase serum. Following primary and secondary dengue infections, there is a relatively transient appearance of antIVENUS (immunoglobulin [Ig] M) antibodies. These disappear after 6-12 wk, a feature that can be used to time a dengue infection. In secondary dengue infections, most antibody is of the IgG class. Serologic diagnosis depends on a 4-fold or greater increase in IgG antibody titer in paired sera by hemagglutination inhibition, complement fixation, enzyme immunoassay, or neutralization test. Carefully standardized IgM and IgG capture enzyme immunoassays are now widely used to identify acute-phase antibodies from patients with primary or secondary dengue infections in single-serum samples. Usually such samples should be collected not earlier than 5 days and not later than 6 wk after onset. It may not be possible to distinguish the infecting virus by serologic methods alone, particularly when there has been prior infection with another member of the same arbovirus group. Virus can be recovered from acute-phase serum after inactivating tissue culture or living mosquitoes. Viral RNA can be detected in blood or tissues by specific complementary RNA probes or amplified first by polymerase chain reaction or by real-time polymerase chain reaction. A viral nonstructural protein, NS1, is released by infected cells into the circulation and can be detected in acute-stage blood samples using monoclonal or polyclonal antibodies. The detection of NS1 is the basis of commercial tests, including rapid lateral flow tests. These tests offer reliable point of care diagnosis of acute dengue infection.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of dengue fever includes dengue-like diseases, viral respiratory and influenza-like diseases, the early stages of malaria, mild yellow fever, scrub typhus, viral hepatitis, and leptospirosis.

Four arboviral diseases have dengue-like courses but without rash: Colorado tick fever, sandfly fever, Rift Valley fever, and Ross River fever. Colorado tick fever occurs sporadically among campers and hunters in the western United States; sandfly fever in the Mediterranean region, the Middle East, southern Russia, and parts of the Indian subcontinent; and Rift Valley fever in North, East, Central, and South Africa. Ross River fever is endemic in much of eastern Australia, with epidemic extension to Fiji. In adults, Ross River fever often produces protracted and crippling arthralgia involving weight-bearing joints. Because meningococcemia, yellow fever (see Chapter 270), other viral hemorrhagic fevers (see Chapter 271), many rickettsial diseases, and other severe illnesses caused by a variety of agents may produce a clinical picture similar to dengue hemorrhagic fever, the etiologic diagnosis should be made only when epidemiologic or serologic evidence suggests the possibility of a dengue infection.

LABORATORY FINDINGS

In dengue fever, pancytopenia may develop after the 3-4 days of illness. Neutropenia may persist or reappear during the latter stage of the disease and may continue into convalescence, with white blood cell counts <2,000/µL. Platelet counts rarely fall below 100,000/µL. Venous clotting, bleeding and prothrombin times, and plasma fibrinogen values are within normal ranges. The tourniquet test result may be positive. Mild acidosis, hemoconcentration, increased transaminase values, and hypoprothrominemia may occur during some primary dengue virus infections. The electrocardiogram may show sinus bradycardia, ectopic ventricular foci, flattened T waves, and prolongation of the P-R interval.

The most common hematologic abnormalities during dengue hemorrhagic fever and dengue shock syndrome are hemoconcentration with an increase of >20% in hematocrit, thrombocytopenia, prolonged bleeding time, and a moderately decreased prothrombin level that is seldom <40% of control. Fibrinogen levels may be subnormal, and fibrin split-product values are elevated. Other abnormalities include moderate elevations of serum transaminase levels, consumption of complement, mild metabolic acidosis with hyponatremia, occasionally hypochloremia, slight elevation of serum urea nitrogen, and hypoalbuminemia. Roentgenograms of the chest reveal pleural effusions (right > left) in nearly all patients with dengue shock syndrome. Ultrasonography can be used to detect serumal effusions of the thorax or abdomen. Thickening of gallbladder wall and presence of perivesical fluid are characteristic signs of increased vascular permeability.

TREATMENT

Treatment of uncomplicated dengue fever is supportive. Bed rest is advised during the febrile period. Antipyretics should be used to keep body temperature <40°C (104°F). Analgesics or mild sedation may be required to control pain. Aspirin is contraindicated and should not be used because of its effects on hemostasis. Fluid and electrolyte replacement is required for deficits caused by sweating, fasting, thirsting, vomitting, and diarrhea.

Dengue Hemorrhagic Fever and Dengue Shock Syndrome

Dengue shock syndrome is a medical emergency that may occur in any child with a recent travel history to a tropical destination. Management begins with diagnostic suspicion and the understanding that shock often occurs during defervescence. Detailed instructions for case management are available at the Geneva or New Delhi World Health Organization websites: http://www.who.int/csr/don/archive/disease/dengue_fever/dengue.pdf. Management of dengue hemorrhagic fever and dengue shock syndrome includes immediate evaluation of vital signs and degrees of hemoconcentration, dehydration, and electrolyte imbalance. Close monitoring is essential for at least 48 hr, because shock may occur or recur precipitously early in the disease. Patients who are cyanotic or have labored breathing should be given oxygen. Rapid intravenous replacement of fluids and electrolytes can frequently sustain patients until spontaneous recovery occurs. Normal saline is more effective than the more expensive Ringer lactated saline in treating shock. When pulse pressure is ≤10 mm Hg or when elevation of the hematocrit persists after replacement of fluids, plasma or colloid preparations are indicated.

Care must be taken to avoid overhydration, which may contribute to cardiac failure. Transfusions of fresh blood or platelets suspended in plasma may be required to control bleeding; they should not be given during hemoconcentration but only after evaluation of hemoglobin or hematocrit values. Salicylates are contraindicated because of their effect on blood clotting.

Sedation may be required for children who are markedly agitated. Use of vasopressors has not resulted in a significant reduction of mortality among those observed with simple supportive therapy. Disseminated intravascular coagulation may require treatment (see Chapter 483). Corticosteroids do not shorten the duration of disease or improve prognosis in children receiving careful supportive therapy.

COMPlications

Hypervolemia during the fluid reabsorptive phase may be life-threatening and is heralded by a decrease in hematocrit with wide pulse pressure. Diuretics and digitalization may be necessary.

Primary infections with dengue fever and dengue-like diseases are usually self-limited and benign. Fluid and electrolyte losses, hyperpyrexia, and febrile convulsions are the most frequent complications in infants and young children. Epistaxis, petechiae, and purpuric lesions are uncommon but may occur at any stage. Blood from epis-taxis that is swallowed, vomited, or passed by rectum may be erroneously interpreted as gastrointestinal bleeding. In adults and possibly in children, underlying conditions may lead to clinically significant bleeding. Convulsions may occur during high temperature, especially with chikungunya fever. Infrequently, after the febrile stage, prolonged asthenia, mental depression, bradycardia, and ventricular extrasystoles may occur in children.

In endemic areas, dengue hemorrhagic fever should be suspected in children with a febrile illness suggestive of dengue fever who experience hemoconcentration and thrombocytopenia.
**PROGNOSIS**

**Dengue Fever**
The prognosis is good. Care should be taken to avoid use of drugs that suppress platelet activity.

**Dengue Hemorrhagic Fever**
The prognosis of dengue hemorrhagic fever is adversely affected by late diagnosis and delayed or improper treatment. Death has occurred in 40-50% of patients with shock, but with adequate intensive care, deaths should occur in <1% of cases. Infrequently, there is residual brain damage as a consequence of prolonged shock or occasionally of intracranial hemorrhage. Many fatalities are caused by overhydration.

**PREVENTION**
Several types of dengue type 1-4 vaccines are under development, and a killed vaccine for chikungunya is efficacious but not licensed. Large-scale Phase III clinical evaluations of a chimeric yellow fever/dengue tetravalent vaccine manufactured by Sanofi Pasteur reveal only moderate protection against individual dengue viruses but a reduction in hospitalization and severe disease. Other major vaccine manufacturers, GlaxoSmithKline, Takeda and Merck, have other tetravalent dengue vaccines in human clinical trials. Sanofi plans to license their vaccine first in dengue-endemic countries. The possibility exists that incomplete dengue immunization may sensitize recipients, with the potential that ensuing dengue infections could result in dengue hemorrhagic fever. Prophylaxis consists of avoiding daytime household-based mosquito bites through the use of insecticides, repellents, body covering with clothing, screening of houses, and destruction of *A. aegypti* breeding sites. If water storage is mandatory, a tight-fitting lid or a thin layer of oil may prevent egg laying or hatching. A larvicide, such as Abate (O,O′-[thiodi-p-phenylene] O,O,O′-tetramethyl phosphorothioate), available as a 1% sand-granule formation and effective at a concentration of 1 ppm, may be added safely to drinking water. Ultra-low-volume spray equipment effectively dispenses the adulticide malathion from truck or airplane for rapid intervention during an epidemic. Only mosquito repellants and other personal antimosquito measures are effective against mosquitoes in the field, forest, or jungle.

*Bibliography is available at Expert Consult.*
Bibliography

Yellow fever is an acute infection characterized in its most severe form by fever, jaundice, proteinuria, and hemorrhage. The virus is mosquitoborne and occurs in epidemic or endemic form in South America and Africa. Seasonal epidemics occurred in cities located in temperate areas of Europe and the Americas until 1900, and epidemics continue in West, Central, and East Africa.

ETILOGY

Yellow fever is the prototype of the Flavivirus genus of the family Flaviviridae, which are enveloped single-stranded RNA viruses 35–50 nm in diameter.

Yellow fever circulates zoonotically as 5 genotypes: type IA in West Central Africa, type IB in South America, type II in West Africa, type III in East Central Africa, and type IV in East Africa. Types IA and IB virus are capable of urban transmission between human beings by Aedes aegypti. Sometime in the 1600s yellow fever virus was brought to the American tropics through the African slave trade. Subsequently, yellow fever caused enormous coastal and riverine epidemics in the Atlantic and Caribbean basins until the 20th century, when the virus and its urban and sylvan mosquito cycles were identified, mosquito control methods were perfected, and a vaccine was developed. The East and East/Central African genotypes have not fully entered the urban cycle and have not spread to the East Coast of Africa or to the countries of Asia.

EPIDEMIOLOGY

Human and nonhuman primate hosts acquire the yellow fever infection by the bite of infected mosquitoes. After an incubation period of 3–6 days, virus appears in the blood and may serve as a source of infection for other mosquitoes. The virus must replicate in the gut of the mosquito and pass to the salivary gland before the mosquito can transmit the virus. Yellow fever virus is transmitted in an urban cycle—human to A. aegypti to human—and a jungle cycle—monkey to jungle mosquitoes to monkey. Classic yellow fever epidemics in the United States, South America, the Caribbean, and parts of Europe were of the urban variety. Since 2000, West Africa has experienced 5 urban epidemics, including in the capital cities of Abidjan (Cote d’Ivoire), Conakry (Guinea), and Dakar (Senegal). In 2012–2013, large outbreaks of East and East/Central yellow fever occurred across a large, predominantly rural area of war-ravaged Darfur in southwestern Sudan and in adjacent areas of northern Uganda. Most of the approximately 200 cases reported each year in South America are jungle yellow fever. In colonial times, urban yellow fever attack rates in white adults were very high, suggesting that subclinical infections are uncommon in this age group. Yellow fever may be less severe in children, with subclinical infection: clinical case ratios ≥2:1. In areas where outbreaks of urban yellow fever are common, most cases involve children because many adults are immune. Transmission in West Africa is highest during the rainy season, from July to November. The migration of nonimmune laborers into endemic regions is a significant factor in some outbreaks.

In tropical forests, yellow fever virus is maintained in a transmission cycle involving monkeys and tree hole–breeding mosquitoes (Haemagogus in Central and South America; the Aedes africanus complex in Africa). In the Americas, most cases involve tourists, campers, and men who work in forested areas and are exposed to infected mosquitoes. In Africa, the virus is prevalent in moist savanna and savanna transition areas, where other tree hole–breeding Aedes vectors transmit the virus between monkeys and humans and between humans.

PATHOGENESIS

Pathologic changes seen in the liver include: (1) coagulative necrosis of hepatocytes in the midzone of the liver lobule, with sparing of cells around the portal areas and central veins; (2) eosinophilic degeneration of hepatocytes (Councilman bodies); (3) microvacuolar fatty change; and (4) minimal inflammation. The kidneys show acute tubular necrosis. In the heart, myocardial fiber degeneration and fatty infiltration are seen. The brain may show edema and petechial hemorrhages. Direct viral injury to the liver results in impaired ability to perform functions of biosynthesis and detoxification; this is the central pathogenic event of yellow fever. Hemorrhage is postulated to result from decreased synthesis of vitamin K–dependent clotting factors and, in some cases, disseminated intravascular clotting. However, because the pathogenesis of shock in patients with yellow fever appears similar to that described for dengue shock syndrome and the other viral hemorrhagic fevers, viral damage to platelets and endothelial cells resulting in release of prohemorrhagic factors may be the central mechanism of hemorrhage in yellow fever.

Renal dysfunction has been attributed to hemodynamic factors (pre-renal failure progressing to acute tubular necrosis).

CLINICAL MANIFESTATIONS

In Africa, inapparent, abortive, or clinically mild infections are frequent; some studies suggest that children experience a milder disease than adults do. Abortive infections, characterized by fever and headache, may be unrecognized except during epidemics.

In its classic form, yellow fever begins with sudden onset of fever, headache, myalgia, lumbosacral pain, anorexia, nausea, and vomiting. Physical findings during the early phase of illness, when virus is present in the blood, include prostration, conjunctival injection, flushing of
face and neck, reddening of the tongue at the tip and edges, and relative bradycardia. After 2-3 days, there may be a brief period of remission, followed in 6-24 hr by reappearance of fever with vomiting, epigastric pain, jaundice, dehydration, gastrointestinal and other hemorrhages, albuminuria, hypotension, renal failure, delirium, convulsions, and coma. Death may occur after 7-10 days, with the fatality rate in severe cases approaching 50%. Some patients who survive the acute phase of illness later succumb to renal failure or myocardial damage. Laboratory abnormalities include leukopenia; prolonged clotting, prothrombin, and partial thromboplastin times; thrombocytopenia; hyperbilirubinemia; elevated serum transaminase values; albuminuria; and azotemia. Hypoglycemia may be present in severe cases. Electrocardiogram abnormalities such as bradycardia and ST-T changes are described.

**DIAGNOSIS**

Yellow fever should be suspected when fever, headache, vomiting, myalgia, and jaundice appear in residents of enzootic areas or in unimmunized visitors who have recently traveled (within 2 wk before onset of symptoms) to endemic areas. Clinically, yellow fever is quite similar to dengue hemorrhagic fever. In contrast to the gradual onset of acute viral hepatitis resulting from hepatitis A, B, C, D, or E virus, jaundice in yellow fever appears after 3-5 days of high temperature and is often accompanied by severe prostration. Mild yellow fever is dengue-like and cannot be distinguished from a wide variety of other infections. Jaundice and fever may occur in any of several other tropical diseases, including malaria, viral hepatitis, louse-borne relapsing fever, leptospirosis, typhoid fever, rickettsial infections, certain systemic bacterial infections, sickle cell crisis, Rift Valley fever, Crimean-Congo hemorrhagic fever, and other viral hemorrhagic fevers. Outbreaks of yellow fever always include cases with severe gastrointestinal hemorrhage.

Specific diagnosis depends on detection of virus or viral antigen in acute-phase blood samples or antibody assays. The immunoglobulin M enzyme immunoassay is particularly useful. Sera obtained during the 1st 10 days after onset of symptoms should be kept in an ultra-low-temperature freezer (−70°C [−94°F]) and shipped on dry ice for virus testing. Convalescent-phase samples for antibody tests are managed by conventional means. In handling acute-phase blood specimens, medical personnel must take care to avoid contaminating themselves or others on the evacuation trail (laboratory personnel and others). Postmortem diagnosis is based on virus isolation from liver or blood, identification of Councilman bodies in liver tissue, or detection of antigen or viral genome in liver tissue.

**TREATMENT**

It is customary to keep patients with yellow fever in a mosquito-free area, with use of mosquito nets if necessary. Patients are viremic during the febrile phase of the illness. Although there is no specific treatment for yellow fever, medical care is directed at maintaining physiologic status with the following measures: (1) sponging and acetaminophen to reduce high temperature, (2) vigorous fluid replacement of losses resulting from fasting, thirsting, vomiting, or plasma leakage, (3) correcting acid–base imbalance, (4) maintaining nutritional intake to lessen the severity of hypoglycemia, and (5) avoiding drugs that are either metabolized by the liver or toxic to the liver, kidney, or central nervous system.

**COMPLICATIONS**

Complications of acute yellow fever include severe hemorrhage, liver failure, and acute renal failure. Bleeding should be managed by transfusion of fresh whole blood or fresh plasma with platelet concentrates if necessary. Renal failure may require peritoneal dialysis or hemodialysis.

**PREVENTION**

Yellow fever 17D is a live-attenuated vaccine with a long record of safety and efficacy. It is administered as a single 0.5 mL subcutaneous injection at least 10 days before arrival in a yellow fever–endemic area. With the exceptions noted later, individuals traveling to endemic areas in South America and Africa should be considered for vaccination, but length of stay, exact locations to be visited, and environmental or occupational exposure may determine the specific risk and individual need for vaccination. Persons traveling from yellow fever–endemic to yellow fever–receptive countries may be required by national authorities to obtain a yellow fever vaccine (e.g., from South America or Africa to India). Usually countries that require travelers to obtain a yellow fever immunization do not issue a visa without a valid immunization certificate. Vaccination is valid for 10 yr for international travel certification, although immunity lasts at least 40 yr and probably for life. Immunoglobulin M antibodies circulate for years after administration of yellow fever vaccine.

Since 1996, there have been a number of reports of **yellow fever vaccine–associated viscerotropic disease** with higher risk in elderly vaccine recipients and in persons with previous thymectomies. Yellow fever vaccine should not be administered to persons who have symptomatic immunodeficiency diseases, are taking immunosuppressant drugs, or have a history of thymectomy. A recent study has shown that individuals on maintenance corticosteroids may be successfully vaccinated. Although the vaccine is not known to harm fetuses, its administration during pregnancy is not advised. The vaccine virus may be rarely transmitted through breastfeeding. In very young children, there is a small risk of encephalitis and death after yellow fever 17D vaccination. The 17D vaccine should not be administered to infants younger than 4 mo. Residence in or travel to areas of known or anticipated yellow fever activity (e.g., forested areas in the Amazon basin), which puts an individual at high risk, warrants immunization of infants 4-9 mo of age. Immunization of children 9 mo of age and older is routinely recommended before entry into endemic areas. Immunization of persons older than 60 yr of age should be weighed against their risk for sylvatic yellow fever in the American tropics and for urban or sylvatic yellow fever in Africa. Vaccination should be avoided in persons with a history of egg allergy. Alternatively, a skin test can be performed to determine whether a serious allergy exists that would preclude vaccination.

Ebola and Other Viral Hemorrhagic Fevers

Scott B. Halstead

Viral hemorrhagic fevers are a loosely defined group of clinical syndromes in which hemorrhagic manifestations are either common or especially notable in severe illness. Both the etiologic agents and clinical features of the syndromes differ, but disseminated intravascular coagulopathy may be a common pathogenetic feature.

ETIOLOGY

Six of the viral hemorrhagic fevers are caused by arthropod-borne viruses (arboviruses) (Table 271-1). Four are caused by togaviruses of the family Flaviviridae: Kyasanur Forest disease, Omsk hemorrhagic fever, dengue (see Chapter 269), and yellow fever (see Chapter 270) viruses. Three are caused by viruses of the family Bunyaviridae: Congo fever, Hantaan fever, and Rift Valley fever (RVF) viruses. Four are caused by viruses of the family Arenaviridae: Junin fever, Machupo fever, Guanarito fever, and Lassa fever. Two are caused by viruses of the family Filoviridae: Ebola and Marburg disease. The Filoviridae are enveloped, filamentous RNA viruses that are sometimes branched, unlike any other known virus.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

With some exceptions, the viruses causing viral hemorrhagic fevers are transmitted to humans via a nonhuman entity. The specific ecosystem
required for viral survival determines the geographic distribution of disease. Although it is commonly thought that all viral hemorrhagic fevers are arthropod borne, 7 may be contracted from environmental contamination caused by animals or animal cells or from infected humans (see Table 271-1). Laboratory and hospital infections have occurred with many of these agents. Lassa fever and Argentine and Bolivian hemorrhagic fevers are reportedly milder in children than in adults.

**Crimean-Congo Hemorrhagic Fever**

Sporadic human infection with Crimean-Congo hemorrhagic fever in Africa provided the original virus isolation. Natural foci are recognized in Bulgaria, western Crimea, and the Rostov-on-Don and Astrakhan regions; disease occurs in Central Asia from Kazakhstan to Pakistan. Index cases were followed by nosocomial transmission in Pakistan and Afghanistan in 1976, in the Arabian Peninsula in 1983, and in South Africa in 1984. In the Russian Federation, the vectors are ticks of the species *Haemaphysalis turturis* and *Haemaphysalis spinigera*, which, along with hares and birds, may serve as viral reservoirs. Disease occurs from June to September, largely among farmers and dairy workers.

**Kyasanur Forest Disease**

Human cases of Kyasanur Forest disease occur chiefly in adults in an area of Mysore State, India. The main vectors are 2 Ixodidae ticks, *Haemaphysalis spinigera* and *Haemaphysalis turturis*. Monkeys and forest rodents may be amplifying hosts. Laboratory infections are common.

**Omsk Hemorrhagic Fever**

Omsk hemorrhagic fever occurs throughout south-central Russia and northern Romania. Vectors may include *Dermacentor pictus* and *Dermacentor marginatus*, but direct transmission from moles and muskrats to humans seems well established. Human disease occurs in a spring-summer-autumn pattern, paralleling the activity of vectors. This infection occurs most frequently in persons with outdoor occupational exposure. Laboratory infections are common.

**Rift Valley Fever**

The virus causing RVF is responsible for epizootics involving sheep, cattle, buffalo, certain antelopes, and rodents in North, Central, East, and South Africa. The virus is transmitted to domestic animals by *Culex theileri* and several *Aedes* species. Mosquitoes may serve as reservoirs by transovarial transmission. An epizootic in Egypt in 1977-1978 was accompanied by thousands of human infections, principally among veterinarians, farmers, and farm laborers. Smaller outbreaks occurred in Senegal in 1987, Madagascar in 1990, and Saudi Arabia and Yemen in 2000-2001. Humans are most often infected during the slaughter or skinning of sick or dead animals. Laboratory infection is common.

* Patients may be contagious; nosocomial infections are common.
†Chikungunya virus is associated infrequently with petechiae and epistaxis. Severe hemorrhagic manifestations have been reported in some cases.

---

**Argentine Hemorrhagic Fever**

Before introduction of vaccine, hundreds to thousands of cases of Argentine hemorrhagic fever occurred annually from April through July in the maize-producing area northwest of Buenos Aires that reaches to the eastern margin of the Province of Cordoba. Junin virus has been isolated from the rodents *Mus musculus*, *Akodon arenicola*, and *Calomys laucha laucha*. It infects migrant laborers who harvest the maize and who inhabit rodent-contaminated shelters.

**Bolivian Hemorrhagic Fever**

The recognized endemic area of Bolivian hemorrhagic fever consists of the sparsely populated province of Beni in Amazonian Bolivia. Sporadic cases occur in farm families who raise maize, rice, yucca, and beans. In the town of San Joaquin, a disturbance in the domestic rodent ecosystem may have led to an outbreak of household infection caused by Machupo virus transmitted by chronically infected *Calomys callosus*, ordinarily a field rodent. Mortality rates are high in young children.

**Venezuelan Hemorrhagic Fever**

In 1989, an outbreak of hemorrhagic illness occurred in the farming community of Guanarito, Venezuela, 200 miles south of Caracas. Subsequently, in 1990-1991, there were 104 cases reported with 26 deaths caused by Guanarito virus. Cotton rats (*Sigmodon alstoni*) and cane rats (*Zygodontomys brevicauda*) have been implicated as likely reservoirs of Venezuelan hemorrhagic fever.

**Lassa Fever**

Lassa virus has an unusual potential for human-to-human spread, which has resulted in many small epidemics in Nigeria, Sierra Leone, and Liberia. In 2012, an outbreak of more than 1,000 cases of Lassa fever occurred in east-central Nigeria. Medical workers in Africa and the United States have also contracted the disease. Patients with acute Lassa fever have been transported by international aircraft, necessitating extensive surveillance among passengers and crews. The virus is probably maintained in nature in a species of African peridomestic rodent, *Mus musculus*. Rodent-to-human transmission and infection of humans probably operate via mechanisms established for other arenaviruses.

**Marburg Disease**

Until recently, the world experience of Marburg disease had been limited to 26 primary and 5 secondary cases in Germany and Yugoslavia in 1967, and to small outbreaks in Zimbabwe in 1975, Kenya in 1980 and 1988, and South Africa in 1983. However, in 1999 a large outbreak occurred in Congo Republic and in 2005 a still larger outbreak occurred in Uige Province, Angola, with 252 cases and 227 deaths. In laboratory and clinical settings, transmission occurs by direct contact with tissues of the African green monkey or with infected human blood or semen. A reservoir in bats has been demonstrated. It appears that the virus is transmitted by close contact between fructivorous bats and from bats by aerosol to humans.

**Ebola Hemorrhagic Fever**

Ebola virus was isolated in 1976 from a devastating epidemic involving small villages in northern Zaire and southern Sudan; smaller outbreaks have occurred subsequently. Outbreaks have initially been nosocomial. Attack rates have been highest in the birth-1 yr old and 15-50 yr old age groups. The virus is closely related to Marburg virus. Ebola virus epizootics have occurred in Kikwit, Zaire, in 1995, followed by scattered outbreaks in Uganda and Central and West Africa. The virus has been recovered from chimpanzees, and antibodies have been found in other subhuman primates, which apparently acquire infection from a zoonotic reservoir in bats. The mode of transmission to humans is unknown. Reston virus, related to Ebola virus, has been recovered from Philippine monkeys and pigs and has caused subclinical infections in workers in monkey colonies in the United States.

West Africa in 2014 has experienced the largest number of cases of Ebola virus disease (EVD), with more than 17,900 cases reported as of December 2014 (Fig. 271-1). Countries primarily affected are Liberia, Sierra Leone, and Guinea, with imported cases reported in Nigeria,
Mali, and Senegal as well as Europe and the United States. Of the 3 strains of EVD (Zaire, Sudan, Bundibugyo), the new strain in Zaire has a mortality rate of approximately 55-65%.

EVD may occur following exposure to fruit bats or bushmeat but most often occurs through exposure to body fluids (blood, sweat, saliva, vomitus, diarrhea, and less often human milk or semen). Patients are infectious once they are symptomatic; the incubation period is 2-21 days (mean: 11 days). The age range in the West African epidemic is broad but most patients are between 15 and 44 yr old.

Manifestations of EVD may come in stages, but most EVD begins with the sudden onset of fever accompanied by fatique, weakness, myalgia, headache, and sore throat. This is followed by gastrointestinal involvement including anorexia, nausea, abdominal pain, vomiting, and diarrhea. Hemorrhage (defined by any evidence of bleeding) is seen in more than 50% and is a serious later phase often accompanied by vascular leakage, multiorgan failure, and death. Those who survive improve on approximately days 6-11 of EVD.

The diagnosis is confirmed by enzyme-linked immunosorbent assay immunoglobulin M and polymerase chain reaction (which may need to be repeated if initially negative). The differential diagnosis includes malaria, typhoid, Lassa fever, influenza, and meningococcemia. Criteria to aid in the diagnosis of EVD include temperature >38.6°C (101.5°F) plus symptoms: contact with an affected patient, the patient's body fluids, or the funeral; residence in or travel to an endemic region; or a history of handling bats, rodents, or primates from an endemic area.

Treatment of EVD often requires an intensive care unit and management of multiorgan system dysfunction, including fluid replacement and ventilation support. Convalescent serum and monoclonal antibodies have been employed on an experimental basis. Strict isolation and appropriate barrier protection of healthcare workers is mandatory. There is no vaccine, and epidemic measures, isolation, and quarantine have been used to attempt to decrease the spread of the West African epidemic.

**Hemorrhagic Fever with Renal Syndrome**

The endemic area of hemorrhagic fever with renal syndrome (HFRS), also known as *epidemic hemorrhagic fever* and *Korean hemorrhagic fever*, includes Japan, Korea, far eastern Siberia, north and central China, European and Asian Russia, Scandinavia, Czechoslovakia, Romania, Bulgaria, Yugoslavia, and Greece. Although the incidence and severity of hemorrhagic manifestations and the mortality are lower in Europe than in northeastern Asia, the renal lesions are the same. Disease in Scandinavia, *nephropathia epidemica*, is caused by a different although antigenically related virus, Puumala virus, associated with the bank vole, *Clethrionomys glareolus*. Cases occur predominantly in the spring and summer. There appears to be no age factor in susceptibility, but because of occupational hazards, young adult men are most frequently attacked. Rodent plagues and evidence of rodent infestation have accompanied endemic and epidemic occurrences. Hantaan virus has been detected in lung tissue and excreta of *Apodemus agrarius coreae*. Antigenically related agents have been detected in laboratory rats and in urban rat populations around the world, including Prospect Hill virus in the wild rodent *Microtus pennsylvanicus* in North America and *sin nombre* virus in the deer mouse in the southern and southwestern United States; these viruses are causes of hantavirus pulmonary syndrome (see Chapter 273). Rodent-to-rodent and rodent-to-human transmission presumably occurs via the respiratory route.

**CLINICAL MANIFESTATIONS**

Dengue hemorrhagic fever (see Chapter 269) and yellow fever (see Chapter 270) cause similar syndromes in children in endemic areas.

**Crimean-Congo Hemorrhagic Fever**

The incubation period of 3-12 days is followed by a febrile period of 5-12 days and a prolonged convalescence. Illness begins suddenly with fever, severe headache, myalgia, abdominal pain, anorexia, nausea, and vomiting. After 1-2 days, fever may subside until the patient experiences an erythematous facial or truncal flush and injected conjunctivae. A second febrile period of 2-6 days then develops, with a hemorrhagic enanthem on the soft palate and a fine petechial rash on the chest and abdomen. After 1-2 days, fever may subside until the patient experiences an erythematous facial or truncal flush and injected conjunctivae. A second febrile period of 2-6 days then develops, with a hemorrhagic enanthem on the soft palate and a fine petechial rash on the chest and abdomen. Less frequently, there are large areas of purpura and bleeding from the gums, nose, intestines, lungs, or uterus. Hematura and proteinuria are relatively rare. During the hemorrhagic stage, there is usually tachycardia with diminished heart sounds and occasionally hypotension. The liver is usually enlarged, but there is no icterus. In protracted cases, central nervous system signs include delirium, somnolence, and progressive clouding of consciousness. Early in the disease, leukopenia with relative lymphocytosis, progressively worsening thrombocytopenia, and gradually increasing anemia occur. In convalescence there may be hearing and memory loss. The mortality rate is 2-50%.

**Kyasanur Forest Disease and Omsk Hemorrhagic Fever**

After an incubation period of 3-8 days, both Kyasanur Forest disease and Omsk hemorrhagic fever begin with sudden onset of fever and headache. Kyasanur Forest disease is characterized by severe myalgia, prostration, and bronchiolar involvement; it often manifests without hemorrhage but occasionally with severe gastrointestinal bleeding. In Omsk hemorrhagic fever, there is moderate epistaxis, hematemesis,
and a hemorrhagic enanthem but no profuse hemorrhage; bronchopneumonia is common. In both diseases, severe leukopenia and thrombocytopenia, vascular dilation, increased vascular permeability, gastrointestinal hemorrhages, and subserosal and interstitial petechial hemorrhages occur. Kyasaru Forest disease may be complicated by acute degeneration of renal tubules and focal liver damage. In many patients, recurrent febrile illness may follow an afebrile period of 7-15 days. This 2nd phase takes the form of a meningoencephalitis.

**Rift Valley Fever**

Most RVF infections have occurred in adults with signs and symptoms resembling those of dengue fever (see Chapter 269). Onset is acute, with fever, headache, prostration, myalgia, anorexia, nausea, vomiting, conjunctivitis, and lymphadenopathy. The fever lasts 3-6 days and is often biphasic. Convalescence is often prolonged. In the 1977-1978 outbreak many patients died after showing signs that included purpura, epistaxis, hematemesis, and melena. RVF affects the uvea and posterior chorioretina; macular scarring, vascular occlusion, and optic atrophy occur, resulting in permanent visual loss in a high proportion of patients with mild to severe RVF. At autopsy extensive eosinophilic degeneration of the parenchymal cells of the liver has been observed.

**Argentine, Venezuelan, and Bolivian Hemorrhagic Fevers and Lassa Fever**

The incubation period in Argentine, Venezuelan, and Bolivian hemorrhagic fevers and Lassa fever is commonly 7-14 days; the acute illness lasts for 2-4 wk. Clinical illnesses range from undifferentiated fever to the characteristic severe illness. Lassa fever is most often clinically severe in white persons. Onset is usually gradual, with increasing fever, headache, diffuse myalgia, and anorexia (Table 271-2). During the 1st wk, signs frequently include a sore throat, dysphagia, cough, oropharyngeal ulcers, nausea, vomiting, diarrhea, and pains in the chest and abdomen. Pleuritic chest pain may persist for 2-3 wk. In Argentine and Bolivian hemorrhagic fevers and less frequently in Lassa fever, a petechial enanthem appears on the soft palate 3-5 days after onset and at about the same time on the trunk. The tourniquet test may be positive. The clinical course of Venezuelan hemorrhagic fever has not been well described.

In 35-50% of all patients, these diseases may become severe, with persistent high temperature, increasing toxicity, swelling of the face or neck, microscopic hematuria, and frank hemorrhages from the stomach, intestines, nose, gums, and uterus. A syndrome of hypovolemic shock is accompanied by pleural effusion and renal failure. Respiratory distress resulting from airway obstruction, pleural effusion, or congestive heart failure may occur. A total of 10-20% of patients experience late neurologic involvement, characterized by intention tremor of the tongue and associated speech abnormalities. In severe cases, there may be intention tremors of the extremities, seizures, and delirium. The cerebrospinal fluid is normal. In Lassa fever, nerve deafness occurs in early convalescence in 25% of cases.

Prolonged convalescence is accompanied by alopechia and, in Argentine and Bolivian hemorrhagic fevers, by signs of autonomic nervous system lability, such as postural hypotension, spontaneous flushing or blanching of the skin, and intermittent diaphoresis.

**Laboratory studies** reveal marked leukopenia, mild to moderate thrombocytopenia, proteinuria, and, in Argentine hemorrhagic fever, moderate abnormalities in blood clotting, decreased fibrinogen, increased fibrinogen split products, and elevated serum transaminases. There is focal, often extensive eosinophilic necrosis of liver parenchyma, focal interstitial pneumonitis, focal necrosis of the distal and collecting tubules, and partial replacement of splenic follicles by amorphous eosinophilic material. Usually bleeding occurs by diapedesis with little inflammatory reaction. The mortality rate is 10-40%.

**Marburg Disease and Ebola Hemorrhagic Fever**

After an incubation period of 4-7 days, illness begins abruptly with severe frontal headache, malaise, drowsiness, lumbar myalgia, vomiting, nausea, and diarrhea. A maculopapular eruption begins 5-7 days later on the trunk and upper arms. It becomes generalized and often hemorrhagic and exfoliates during convalescence. The exanthem is accompanied by a dark red enanthem on the hard palate, conjunctivitis, and scrotal or labial edema. Gastrointestinal hemorrhage occurs as the severity of illness increases. Late in the illness, the patient may become tearfully depressed with marked hyperalgesia to tactile stimuli. In fatal cases, patients become hypotensive, restless, and confused and lapse into coma. Convalescent patients may experience alopecia and may have paresthesias of the back and trunk. There is a marked leukopenia with necrosis of granulocytes. Disseminated intravascular coagulopathy and thrombocytopenia are universal and correlate with severity of disease; there are moderate abnormalities in concentrations of clotting proteins and elevations of serum transaminases and amylase. Pregnant women and young children are at high risk of severe disease with fatal outcome. The mortality rate of Marburg disease is 25-85%, and the mortality rate of Ebola hemorrhagic fever 50-90%. High viral loads in acute-phase blood samples convey a poor prognosis.

**Hemorrhagic Fever with Renal Syndrome**

In most cases, HFRS is characterized by fever, petechiae, mild hemorrhagic phenomena, and mild proteinuria, followed by relatively uneventful recovery. In 20% of recognized cases, the disease may progress through 4 distinct phases. The febrile phase is ushered in with fever, malaise, and facial and truncal flushing. It lasts 3-8 days and ends with thrombocytopenia, petechiae, and proteinuria. The hypotensive phase, of 1-3 days, follows defervescence. Loss of fluid from the intravascular compartment may result in marked hemococoncentration. Proteinuria and ecchymoses increase. The oliguric phase, usually 3-5 days in duration, is characterized by a low output of protein-rich urine, increasing nitrogen retention, nausea, vomiting, and dehydration. Confusion, extreme restlessness, and hypertension are common. The diuretic phase, which may last for days or weeks, usually initiates clinical improvement. The kidneys show little concentrating ability, and rapid loss of fluid may result in severe dehydration and shock. Potassium and sodium depletion may be severe. Fatal cases manifest as abundant protein-rich retroperitoneal edema and marked hemorrhagic necrosis of the renal medulla. The mortality rate is 5-10%.

**DIAGNOSIS**

Diagnosis of these viral hemorrhagic fevers depends on a high index of suspicion in endemic areas. In nonendemic areas, histories of recent travel, recent laboratory exposure, or exposure to an earlier case should evoke suspicion of a viral hemorrhagic fever.

In all viral hemorrhagic fevers, the viral agent circulates in the blood at least transiently during the early febrile stage. Togaviruses and bunyaviruses can be recovered from acute-phase serum samples by inoculation into tissue culture or living mosquitoes. Argentine, Bolivian, and Venezuelan hemorrhagic fever viruses can be isolated from acute-phase blood or throat washings by intracerebral inoculation into guinea pigs, infant hamsters, or infant mice. Lassa virus may be isolated from acute-phase blood or throat washings by inoculation into tissue cultures. For Marburg disease and Ebola hemorrhagic fever,
acute-phase throat washings, blood, and urine may be inoculated into tissue culture, guinea pigs, or monkeys. The viruses are readily identified on electron microscopy, with a filamentous structure differentiating them from all other known agents. Specific complement-fixing and immunofluorescent antibodies appear during convalescence. The virus of HFRS is recovered from acute-phase serum or urine by inoculation into tissue culture. A variety of antibody tests using viral subunits is becoming available. Serologic diagnosis depends on demonstration of seroconversion or a 4-fold or greater increase in immunoglobulin G antibody titer in acute and convalescent serum specimens collected 3-4 wk apart. Viral RNA may also be detected in blood or tissues with use of reverse transcriptase polymerase chain reaction analysis.

Handling blood and other biologic specimens is hazardous and must be performed by specially trained personnel. Blood and autopsy specimens should be placed in tightly sealed metal containers, wrapped in absorbent material inside a sealed plastic bag, and shipped on dry ice to laboratories with biocontainment safety level 4 facilities. Even routine hematologic and biochemical tests should be done with extreme caution.

**Differential Diagnosis**

Mild cases of hemorrhagic fever may be confused with almost any self-limited systemic bacterial or viral infection. More severe cases may suggest typhoid fever; epidemic, murine, or scrub typhus; leptospirosis; or a rickettsial spotted fever, for which effective chemotherapeutic agents are available. Many of these disorders may be acquired in geographic or ecologic locations endemic for a viral hemorrhagic fever.

**TREATMENT**

Ribavirin administered intravenously is effective in reducing mortality rates in Lassa fever and HFRS. Further information and advice about management, control measures, diagnosis, and collection of biohazardous specimens can be obtained from the Centers for Disease Control and Prevention, National Center for Infectious Diseases, Special Pathogens Branch, Atlanta, Georgia 30333 (404-639-1115).

The therapeutic principle involved in all of these diseases, especially HFRS, is the reversal of dehydration, hemoconcentration, renal failure, and protein, electrolyte, or blood losses. The contribution of disseminated intravascular coagulopathy to the hemorrhagic manifestations is unknown, and the management of hemorrhage should be individualized. Transfusions of fresh blood and platelets are frequently given. Good results have been reported in a few patients after the administration of clotting factor concentrates. The efficacy of corticosteroids, ε-aminocaproic acid, pressor amines, and α-adrenergic blocking agents has not been established. Sedatives should be selected with regard to the possibility of kidney or liver damage. The successful management of HFRS may require renal dialysis.

Although whole-blood transfusions from Ebola virus–immune donors are thought to be therapeutic, studies in a monkey model were unable to confirm this outcome.

Patients suspected of having Lassa fever, Ebola fever, Marburg fever, or Congo Crimean hemorrhagic fever should be placed in a private room on standard contact and droplet precautions. Caretakers should use barrier precautions to prevent skin or mucous membrane exposure. All persons entering the patient's room should wear gloves and gowns and face shields. Before exiting the patient’s room, caretakers should safely remove and dispose of all protective gear and should clean and disinfect shoes. Protocols require two-person clinical care teams, one observer and one caregiver. (see CDC website: www.cdc.gov/vhf/ebola/hcp).

**PREVENTION**

A live-attenuated vaccine (Candid-I) for Argentine hemorrhagic fever (Junin virus) is highly efficacious. A form of inactivated mouse brain vaccine is reported to be effective in preventing Omsk hemorrhagic fever. Inactivated RVF vaccines are widely used to protect domestic animals and laboratory workers. HFRS inactivated vaccine is licensed in Korea, and killed and live-attenuated vaccines are widely used in China. A vaccinia-vector glycoprotein vaccine provides protection against Lassa fever in monkeys. A single dose of a recombinant vesicular stomatitis virus vaccine containing surface glycoproteins from Ebola and Marburg viruses is effective in preventing virus hemorrhagic fevers due to several strains of filovirus in a monkey model.

Prevention of mosquito-borne and tick-borne infections includes use of repellents, wearing of tight-fitting clothing that fully covers the extremities, and careful examination of the skin after exposure, with removal of any vectors found. Diseases transmitted from a rodent-infected environment can be prevented through methods of rodent control; elimination of refuse and breeding sites is particularly successful in urban and suburban areas.

Patients should be isolated until they are virus-free or for 3 wk after illness. Patient urine, sputum, blood, clothing, and bedding should be disinfected. Disposable syringes and needles should be used. Prompt and strict enforcement of barrier nursing may be lifesaving. The mortality rate among medical workers contracting these diseases is 50%. A few entirely asymptomatic Ebola infections result in strong antibody production.

*Bibliography is available at Expert Consult.*
Bibliography
Lymphocytic choriomeningitis virus (LCMV) is a prevalent human pathogen and an important cause of meningitis in children and adults. Capable of crossing the placenta and infecting the fetus, LCMV is also an important cause of neurologic birth defects and encephalopathy in the newborn.

**ETIOLOGY**

LCMV is a member of the family Arenaviridae, which are enveloped, negative-sense single-stranded RNA viruses. The name of the arenaviruses is derived from *arenosus*, the Latin word for "sandy," because of the fine granularities observed within the virion on ultrathin electron microscopic sections.

**EPIDEMIOLOGY**

Like all arenaviruses, LCMV utilizes rodents as its reservoir. The common house mouse, *Mus musculus*, is both the natural host and primary reservoir for the virus, which is transferred vertically from 1 generation of mice to the next via intrauterine infection. Hamsters and guinea pigs are also potential reservoirs. Although heavily infected with LCMV, rodents that acquire the virus transplacentally often remain asymptomatic because congenital infection provides rodents with immunologic tolerance for the virus. Infected rodents shed the virus in large quantities in nasal secretions, urine, feces, saliva, and milk throughout their lives. Humans typically acquire LCMV by contacting fomites contaminated with infectious virus or by inhaling aerosolized virus. Most human infections occur during the fall and early winter, when mice move into human habitations. Humans can also acquire the virus via organ transplantation. Congenital LCMV infection occurs when a woman acquires a primary LCMV infection during pregnancy. The virus passes through the placenta to the fetus during maternal viremia. The fetus may also acquire the virus during passage through the birth canal from exposure to infected vaginal secretions. Outside of organ transplantation and vertical transmission during pregnancy, there have been no cases of human-to-human transmission of LCMV.

LCMV is prevalent in the environment, has a great geographic range, and infects large numbers of humans. The virus is found throughout the world's temperate regions and probably occurs wherever the genus *Mus* has been introduced (which is every continent but
Antarctica). An epidemiologic study found that 9% of house mice are infected and that substantial clustering occurs, where the prevalence is higher. Serologic studies demonstrate that approximately 5% of adult humans possess antibodies to LCMV, indicating prior exposure and infection.

**PATHOGENESIS**

LCMV is not a cytoplastic virus. Thus, unlike many other nervous system pathogens that directly damage the brain by killing host brain cells, LCMV pathogenesis involves other underlying mechanisms. Furthermore, the pathogenic mechanisms are different in postnatal (acquired) infection than in prenatal (congenital) infection. A critical difference in the pathogenesis of postnatal vs prenatal infection is that the virus infects brain parenchyma in the case of prenatal infection, but is restricted to the meninges and choroid plexus in postnatal cases.

In postnatal infections, LCMV replicates to high titers in the choroid plexus and meninges. Viral antigen within these tissues becomes the target of an acute mononuclear cell infiltration driven by CD8+ T lymphocytes. The presence of lymphocytes in large numbers within the meninges and cerebrospinal fluid leads to the symptoms of meningitis that mark acquired LCMV infection. As the lymphocytes clear the virus from the meninges and cerebrospinal fluid, the density of lymphocytes declines, and the symptoms of meningitis resolve. Thus, symptoms of acquired (postnatal) LCMV infection are immune mediated and are a result of the presence of large numbers of lymphocytes.

Prenatal infection likewise inflames the tissues surrounding the brain parenchyma, and this inflammation leads to some of the signs of congenital LCMV. In particular, within the ventricular system, congenital LCMV infection often leads to ependymal inflammation, which may block the egress of cerebrospinal fluid (CSF) at the cerebral aqueduct and lead to hydrocephalus. However, unlike postnatal cases, prenatal infection with LCMV includes infection of the substance of the brain rather than just the meninges or ependyma. This infection of brain parenchyma leads to the substantial neuropathologic changes typically accompanying congenital LCMV infection. In particular, LCMV infects the mitotically active neuroblasts, located at periventricular sites. Through an unknown mechanism, presence of the virus kills these periventricular cells, leading to periventricular calcifications, a radiographic hallmark of this disorder. Within the fetal brain, LCMV infection of neurons and glial cells also disrupts neuronal migration, leading to abnormal gyral patterns, and interferes with neuronal mitosis, leading to microcephaly and cerebellar hypoplasia.

**CLINICAL MANIFESTATIONS**

The clinical manifestations of LCMV infection depend on whether the infection occurs prenatally or postnatally. Congenital infection with LCMV is unique, as it involves both the postnatal infection of a pregnant woman and the prenatal infection of a fetus.

**Acquired (Postnatal) Lymphocytic Choriomeningitis Virus Infection**

LCMV infection during postnatal life (during childhood or adulthood) typically consists of a brief febrile illness, from which the patient fully recovers. The illness classically consists of 2 clinical phases. In the 1st phase, the symptoms are those of a nonspecific viral syndrome and usually consist of fever, myalgia, malaise, nausea, anorexia, and vomiting. These symptoms usually resolve after several days but are followed by a 2nd phase, consisting of central nervous system disease. The symptoms of this 2nd phase are those of aseptic meningitis, including headache, fever, nuchal rigidity, photophobia, and vomiting. The entire course of the biphasic disease is typically 1-3 wk.

The clinical spectrum of LCMV infection is broad. One third of postnatal infections are asymptomatic. Other patients develop extraneural disease that extends beyond the usual symptoms and may include orchitis, pneumonia, myocarditis, parotitis, dermatitis, alopecia, and pharyngitis. In others, the neurologic disease may be considerably more severe than usual and may include transverse myelitis, Guillain-Barré syndrome, hydrocephalus, and encephalitis. Recovery from acquired LCMV infection is usually complete, but fatalities occasionally occur.

LCMV infections acquired via solid organ transplantation always induce severe disease. Several weeks posttransplantation, recipients of infected organs develop fever, leukopenia, and lethargy. Following these nonspecific symptoms, the course of disease rapidly progresses to multiorgan system failure and shock. These cases are almost always fatal.

**Congenital Lymphocytic Choriomeningitis Virus Infection**

LCMV infection during pregnancy can kill the fetus and induce spontaneous abortion. Among surviving fetuses, the 2 clinical hallmarks of congenital LCMV infection are vision impairment and brain dysfunction.

The vision impairment in congenital LCMV infection is a result of chorioretinitis and the formation of chorioretinal scars. The scarring is usually bilateral and most commonly located in the periphery of the fundus, but involvement of the macula also occurs.

Although the retinal injuries from congenital LCMV infection are often severe, it is the brain effects that cause the greatest disability. Prenatal infection with LCMV commonly induces either macrocephaly or microcephaly. Macrosephaly following LCMV infection is almost invariably caused by noncommunicating hydrocephalus, stemming from inflammation within the ventricular system. Microcephaly is a result of virus-induced failure of brain growth. In addition to disturbances of head size, periventricular calcifications are also cardinal features of congenital LCMV infection.

Although hydrocephalus, microencephaly, and periventricular calcifications are by far the most commonly observed abnormalities of the brain in congenital LCMV, other forms of neuropathology, alone or in combination, can also occur. These include periventricular cysts, porencephalic cysts, encephalomalacia, intraparenchymal calcifications, cerebellar hypoplasia, and neuronal migration disturbances.

Infants with congenital LCMV infection typically present during the newborn period with evidence of brain dysfunction. The most common signs are lethargy, seizures, irritability, and jitteriness.

Within the fetus, LCMV has a specific tropism for the brain. Thus, unlike many other congenital infections, LCMV usually does not induce systemic manifestations. Birthweight is typically appropriate for gestational age. Skin rashes and thrombocytopenia, which are common in several other prominent congenital infections, are unusual in congenital LCMV infection. Hepatosplenomegaly is only rarely observed, and serum liver enzyme levels are usually normal. Auditory deficits are unusual.

**LABORATORY FINDINGS**

In acquired (postnatal) LCMV infection, the hallmark laboratory abnormality occurs during the 2nd (central nervous system) phase of the disease and is CSF pleocytosis. The CSF typically contains hundreds to thousands of white blood cells, almost all of which are lymphocytes. However, CSF eosinophilia may also occur. Mild elevations of CSF protein and hypoglycorrhachia are common.

In congenital LCMV infection, laboratory findings in the newborn depend on whether the infant is still infected or not. If the infant still harbors the infection, then examination of the CSF may reveal a lymphocytic pleocytosis. Unlike many other congenital infections, LCMV does not typically induce elevations in liver enzymes, thrombocytopenia, or anemia. In many cases, the most reliably abnormal test is the head CT scan, which typically reveals a combination of microencephaly, hydrocephalus, and periventricular calcifications (Fig. 272-1).

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

Acute LCMV infections can be diagnosed by isolating the virus from CSF. Polymerase chain reaction has also been used to detect LCMV RNA in patients with active infections. However, by the time of birth, a baby prenatally infected with LCMV may no longer harbor the virus. Thus, congenital LCMV infection is more commonly diagnosed by serologic testing. The immunofluorescent antibody test detects both immunoglobulin (Ig) M and IgG and has greater sensitivity than the more widely available complement fixation method. The immunofluorescent antibody test is commercially available, and its specificity and sensitivity make it an acceptable diagnostic tool. A more sensitive test for detecting congenital LCMV infection is the enzyme-linked
immunosorbertent assay, which measures titers of LCMV IgG and IgM and is performed at the Centers for Disease Control and Prevention. For acquired (postnatal) LCMV infection, the principal items in the differential diagnosis are the other infectious agents that can induce meningitis. These include bacteria, fungi, viruses, and some other forms of pathogens. The most common viral causes of meningitis are the enteroviruses, including coxsackieviruses and echoviruses, and the arboviruses, including La Crosse encephalitis virus and equine encephalitis virus. Unlike LCMV, which is most common in winter, the enteroviruses and arboviruses are most commonly acquired in summer and early fall.

The principal items in the differential diagnosis of congenital LCMV infection are the other infectious pathogens that can cross the placenta and damage the developing fetus. These infectious agents are linked by the acronym “TORCHS” and include Toxoplasma gondii, rubella virus, cytomegalovirus, herpes simplex virus, and syphilis. Toxoplasmosis and cytomegalovirus infection are particularly difficult to differentiate from LCMV because all 3 of these infectious agents can produce microcephaly, intracerebral calcifications, and chorioretinitis. Although clinical clues may aid in distinguishing a congenital infection from another, definitive identification of the causative infectious agent usually requires laboratory data, including cultures and serologic studies.

COMPLICATIONS
Complications in children with congenital LCMV infection are nonspecific and include the medical problems that commonly arise in scenarios involving ventriculoperitoneal shunts, severe seizure disorders, and static encephalopathy. These complications include shunt failure or infection, aspiration pneumonia, injuries from falls, and joint contractures.

TREATMENT
There is no specific treatment for acquired or congenital LCMV infection. An effective antiviral therapy for LCMV infection has not yet been developed. Ribavirin is active against LCMV and other arenaviruses in vitro, but its utility in vivo is unproven. Immunosuppressive therapy, if present, should be reduced.

SUPPORTIVE CARE
Children with hydrocephalus from congenital LCMV infection often require placement of a ventriculoperitoneal shunt during infancy for treatment of hydrocephalus. Seizures often begin during early postnatal life, are often difficult to control, and require administration of multiple antiepileptic medications. The mental retardation induced by congenital LCMV infection is often profound. In most cases, affected children should be referred for educational intervention during early life. The spasticity accompanying congenital LCMV infection is often severe. Although physical therapy can help to maintain range of motion and minimize painful spasms and contractures, implantation of a baclofen pump is often helpful.

PROGNOSIS
The great majority of patients with postnatally acquired LCMV infection have a full recovery with no permanent sequelae. Rarely, postnatal infections induce hydrocephalus and require shunting. Rarer yet, postnatal LCMV infection is fatal.

In contrast to the usual benign outcome of postnatal infections, prenatal infections typically lead to severe and permanent disability. In children with congenital LCMV infection, brain function is nearly always impaired and chorioretinitis is invariably present. Mental retardation, cerebral palsy, ataxia, epilepsy, and blindness are common neurologic sequelae. However, children with congenital LCMV infection have diverse outcomes. All children with the combination of microencephaly and periventricular calcifications are profoundly neurologically impaired. Blindness, medically refractory epilepsy, spastic quadriparesis, and mental retardation are typical of this group. However, other children with congenital LCMV infection who do not have the combination of microencephaly and periventricular calcifications often have a more favorable outcome, with less severe motor, mental, and vision impairments. Children with isolated cerebellar hypoplasia may be ataxic but have only mild or moderate mental retardation and vision loss.

PREVENTION
No vaccine exists to prevent LCMV infection. However, measures can be taken to reduce the risk of infection. Because rodents, especially house mice, are the principal reservoir of LCMV, people can reduce their risk of contracting LCMV by minimizing their exposure to the secretions and excretions of mice. This can be accomplished most effectively by eliminating cohabitation with mice. Congenital LCMV infection will not occur unless a woman contracts a primary infection with LCMV during pregnancy. Thus, women should be especially careful to avoid contact or cohabitation with mice during pregnancy. Pregnant women should also avoid contact with pet rodents, especially mice and hamsters. These facts should be stressed during prenatal visits.

Acquisition of LCMV from solid organ transplantation represents a substantial risk to organ recipients. Prospective donors with LCMV meningitis or encephalitis pose a clear risk for transmitting a fatal infection to recipients. Healthcare providers, transplantation centers, and organ procurement organizations should be aware of the risks posed by LCMV and should consider LCMV in any potential donor with signs of aseptic meningitis but no identified infectious agent. The risks and benefits of offering and receiving organs from donors with possible LCMV infection should be carefully considered.

Bibliography is available at Expert Consult.
Bibliography
The hantavirus pulmonary syndrome (HPS) is caused by multiple closely related hantaviruses that have been identified from the western United States, with sporadic cases reported from the eastern United States (Fig. 273-1) and Canada and important foci of disease in several countries in South America. HPS is characterized by a febrile
Hantavirus Pulmonary Syndrome Cases, by State of Exposure

Prostate followed by the rapid onset of noncardiogenic pulmonary edema and hypotension or shock. Sporadic cases in the United States caused by related viruses may manifest with renal involvement. Cases in Argentina and Chile sometimes include severe gastrointestinal hemorrhaging; nosocomial transmission has been documented in this geographic region only.

**ETIOLOGY**

Hantaviruses are a genus in the family Bunyaviridae, which are lipid-enveloped viruses with a negative-sense RNA genome composed of 3 unique segments. Several pathogenic viruses that have been recognized within the genus include Hantaan virus, which causes the most severe form of hemorrhagic fever with renal syndrome (HFRS) seen primarily in mainland Asia (see Chapter 271); Dobrava virus, which causes the most severe form of HFRS seen primarily in the Balkans; Puumala virus, which causes a milder form of HFRS with a high proportion of subclinical infections and is prevalent in northern Europe; and Seoul virus, which results in moderate HFRS and is transmitted worldwide by laboratory rats. The diagnosis of HPS should be considered in a previously healthy patient presenting with a febrile prodrome and acute respiratory distress. Occurrence of thrombocytopenia with the febrile prodrome and outdoor exposure in the spring and summer months are strongly suggestive of HPS. Specific diagnosis of HPS is made by serologic tests that detect hantavirus immunoglobulin M antibodies. Early appearance of immunoglobulin G antibodies signals probable recovery. Hantavirus antigen can be detected in tissue by immunohistochemistry and amplification of hantavirus nucleotide sequences detected by reverse transcriptase polymerase chain reaction. The state health department or the Centers for Disease Control and Prevention should be consulted to assist in diagnosis, epidemiologic investigations, and outbreak control.

**CLINICAL MANIFESTATIONS**

HPS is characterized by a prodrome and a cardiopulmonary phase. The mean duration after the onset of prodromal symptoms to hospitalization is 5.4 days. The mean duration of symptoms to death is 8 days (median: 7 days; range: 2-16 days). The most common prodromal symptoms are fever and myalgia (100%); cough or dyspnea (76%); gastrointestinal symptoms, including vomiting, diarrhea, and midabdominal pain (76%); and headache (71%). The cardiopulmonary phase is heralded by progressive cough and shortness of breath. The most common initial physical findings are tachypnea (100%), tachycardia (94%), and hypotension (50%). Rapidly progressive acute pulmonary edema, hypoxia, and shock develop in most severely ill patients. Pulmonary vascular permeability is complicated by cardiogenic shock associated with increased vascular resistance. The clinical course of the illness in patients who die is characterized by pulmonary edema accompanied by severe hypotension, frequently terminating in sinus bradycardia, electromechanical dissociation, ventricular tachycardia, or fibrillation. Hypotension may be progressive even with adequate oxygenation. HPS virus is excreted in the urine during the acute illness phase, and survivors may demonstrate evidence of chronic renal damage.

**DIAGNOSIS**

The diagnosis of HPS should be considered in a previously healthy patient presenting with a febrile prodrome and acute respiratory distress. Occurrence of thrombocytopenia with the febrile prodrome and outdoor exposure in the spring and summer months are strongly suggestive of HPS. Specific diagnosis of HPS is made by serologic tests that detect hantavirus immunoglobulin M antibodies. Early appearance of immunoglobulin G antibodies signals probable recovery. Hantavirus antigen can be detected in tissue by immunohistochemistry and amplification of hantavirus nucleotide sequences detected by reverse transcriptase polymerase chain reaction. The state health department or the Centers for Disease Control and Prevention should be consulted to assist in diagnosis, epidemiologic investigations, and outbreak control.

**LABORATORY FINDINGS**

Laboratory findings include leukocytosis (median: 26,000 cells/μL), elevated hematocrit resulting from hemococoncentration, thrombocytopenia (median: 64,000 cells/μL), prolonged prothrombin and partial
thromboplastin times, elevated serum lactate dehydrogenase concentration, decreased serum protein concentrations, proteinuria, and microscopic hematuria. Patients who die often experience disseminated intravascular coagulopathy including frank hemorrhage and exceptionally high leukocyte counts.

**Differential Diagnosis**
The differential diagnosis includes adult respiratory distress syndrome, pneumonic plague, psittacosis, severe mycoplasmal pneumonia, influenza, leptospirosis, inhalation anthrax, rickettsial infections, pulmonary tularemia, atypical bacterial and viral pneumonial diseases, legionellosis, meningococcemia, and other sepsis syndromes. The key determinant in the diagnosis of HPS is thrombocytopenia.

**TREATMENT**
Management of patients with hantavirus infection requires maintenance of adequate oxygenation and careful monitoring and support of cardiovascular function. The pathophysiology of HPS somewhat resembles that of dengue shock syndrome (see Chapter 269). Pressor or inotropic agents, such as dobutamine, should be administered in combination with judicious volume replacement to treat symptomatic hypotension or shock while avoiding exacerbation of the pulmonary edema. Intravenous ribavirin, which is lifesaving if given early in the course of HFRS and is effective in preventing death in the hamster model, has not yet been demonstrated to be of value in HPS.

Further information and advice about management, control measures, diagnosis, and collection of biohazardous specimens can be obtained from the Centers for Disease Control and Prevention, National Center for Infectious Diseases, Special Pathogens Branch, Atlanta, Georgia 30333 (404-639-1115).

**PROGNOSIS**
In some geographic areas fatality rates for HPS have been 50%. Severe abnormalities in hematocrit, white blood cell count, lactate dehydrogenase value, and partial thromboplastin time, and a high viral load predict death with high specificity and sensitivity. Early appearance of immunoglobulin G antibodies may signal a hopeful prognosis.

**PREVENTION**
Avoiding contact with rodents is the only preventive strategy against HPS. Rodent control in and around the home is important. Barrier nursing is advised, and biosafety level 3 facilities and practices are recommended for laboratory handling of blood, body fluids, and tissues from suspect patients or rodents, because the virus may be aerosolized.

_Bibliography is available at Expert Consult._
Bibliography

Rabies is a bullet-shaped, negative-sense, single-stranded, enveloped RNA virus from the family Rhabdoviridae, genus Lyssavirus. There are currently 12 known genotypes of Lyssavirus, and more are under taxonomic consideration. The classic rabies virus (genotype 1) is distributed worldwide and naturally infects a large variety of animals. The other 6 genotypes are more geographically confined, with none found in the Americas. Seven Lyssavirus genotypes are associated with rabies in humans, although genotype 1 accounts for the great majority of cases. Within genotype 1, a number of genetic variants have been defined. Each variant is specific to a particular animal reservoir, although cross-species transmission can occur.

**EPIDEMIOLOGY**

Rabies is present on all continents except Antarctica. Rabies predominantly afflicts underaged, poor, and geographically isolated populations. Approximately 50,000 cases of human rabies occur in Africa and Asia annually. Theoretically, rabies virus can infect any mammal (which then can transmit disease to humans), but true animal reservoirs that maintain the presence of rabies virus in the population are limited to terrestrial carnivores and bats. Worldwide, transmission from dogs accounts for >90% of human cases. In Africa and Asia, other animals serve as prominent reservoirs, such as jackals, mongooses, and raccoon dogs. In industrialized nations, canine rabies has been largely controlled through the routine immunization of pets. In the United States, raccoons are the most commonly infected wild animal along the eastern seaboard. Three phylogenies of skunk rabies are endemic in the Midwest (north and south) and California, and gray foxes harbor rabies in Arizona and Texas and mongooses in Puerto Rico. Rabies occurs infrequently in livestock. Among American domestic pets, infected cats outnumber infected dogs, probably because cats frequently prowl unsupervised and are not uniformly subject to vaccine laws. Rabies is rare in small mammals, including mice, squirrels, and rabbits; to date, no animal-to-human transmission from these animals has been documented.

The epidemiology of human rabies in the United States is dominated by cryptogenic bat rabies. Bats are migratory in the spring and fall; rabid bats are identified in every state of the union except Hawaii. In 1 study, the largest proportion of cases of human rabies were infected with a bat variant, and in almost all cases of bat-associated human rabies there was no history of a bat bite. Among inhabitants of the Peruvian Amazon region who have exposure to rabies infected vampire bats, there are some who have rabies virus neutralizing antibodies and have survived. Antibody-positive patients remember bat bites but do not recall symptoms of rabies.

In the United States, 30,000 episodes of rabies postexposure prophylaxis (PEP) occur annually. Between 1 and 3 endemic human cases are diagnosed annually, half postmortem. There have been 3 outbreaks of rabies associated with solid-organ and corneal transplantations.

**TRANSMISSION**

Rabies virus is found in large quantities in the saliva of infected animals, and transmission occurs almost exclusively through inoculation of the infected saliva through a bite or scratch from a rabid mammal. Approximately 35-50% of people bitten by a known rabies-infected animal and receiving no PEP contract rabies. The transmission rate is increased if the victim has suffered multiple bites and if the inoculation occurs in highly innervated parts of the body such as the face and the hands. Infection does not occur after exposure of intact skin to infected secretions, but virus may enter the body through intact mucous membranes. Claims that spelunkers may experience rabies after inhaling bat excreta have come under doubt, although inhalational exposure can occur during laboratory accidents.

No case of nosocomial transmission to a healthcare worker has been documented to date, but caregivers of a patient with rabies are advised to use full barrier precautions. The virus is rapidly inactivated in the environment, and contamination of fomites is not a mechanism of spread.

**PATHOGENESIS**

After inoculation, rabies virus replicates slowly and at low levels in muscle or skin. This slow initial step likely accounts for the disease’s long incubation period. Virus then enters the peripheral motor nerve, utilizing the nicotinic acetylcholine receptor and possibly several other receptors for entry. Once in the nerve, the virus travels by fast axonal transport, crossing synapses roughly every 12 hr. Rapid dissemination occurs throughout the brain and spinal cord before symptoms appear. Infection of the dorsal root ganglia is apparently futile but causes characteristic radiculitis. Infection concentrates in the brainstem, accounting for autonomic dysfunction and relative sparing of cognition. Despite severe neurologic dysfunction with rabies, histopathology reveals limited damage, inflammation, or apoptosis. The pathologic
hallmark of rabies, the Negri body, is composed of clumped viral nucleocapsids that create cytoplasmic inclusions on routine histology. Negri bodies can be absent in documented rabies virus infection. Rabies may be a metabolic disorder of neurotransmission; tetrahydrobiopterin deficiency in human rabies causes severe deficiencies in dopamine, norepinephrine, and serotonin metabolism.

After infection of the central nervous system, the virus travels anterograde through the peripheral nervous system to virtually all innervated organs. It is through this route that the virus infects the salivary glands. Many victims of rabies die from uncontrollable cardiac dysrhythmia.

Deficiency of tetrahydrobiopterin, an essential cofactor for neuronal nitric oxide synthase, is predicted to lead to spasm of the basilar arteries. Onset of vasospasm has been confirmed in a few patients within 5-8 days of first hospitalization, at about the time coma supervenes in the natural history. Increased intracranial pressure is regularly measured early in rabies in association with elevated N-acetylaspartate in cerebrospinal fluid (CSF), but is rarely radiologically apparent. Metabolites in CSF consistent with ketogenesis are associated with demise.

**CLINICAL MANIFESTATIONS**

The incubation period for rabies is 1-3 mo, but is variable. In severe wounds to the head, symptoms may occur within 5 days after exposure, and occasionally the incubation period can extend to longer than 6 mo. Rabies has 2 principal clinical forms. **Encephalitic** or **“furious” rabies** begins with nonspecific symptoms, including fever, sore throat, malaise, headache, nausea and vomiting, and weakness. These symptoms are often accompanied by paresthesia and pruritus at or near the site of the bite that then extend along the affected limb. Soon thereafter the patient begins to demonstrate symptoms of encephalitis, with agitation, depressed mentation, and, occasionally, seizures. Characteristically, patients with rabies encephalitis initially have periods of lucidity alternating with periods of profound encephalopathy. Hydrophobia and aerophobia are the cardinal signs of rabies; they are unique to humans and are not universal or specific. Phobic spasms are manifested by agitation and fear created by being offered a drink or fanning of air in the face, which in turn produce choking and aspiration through spasms of the pharynx, neck, and diaphragm. The illness is relentlessly progressive. There is a dissociation of electrophysiologic or encephalographic activity with findings of brainstem coma caused by anterograde denervation. Death almost always occurs within 1-2 days of hospitalization in developing countries and by 18 days of hospitalization with intensive care.

A second form of rabies known as **paralytic** or “dumb” rabies is seen much less frequently and is characterized principally by fevers and ascending motor weakness affecting both the limbs and the cranial nerves. Most patients with paralytic rabies also have some element of encephalopathy as the disease progresses subacutely.

Case reports suggest that milder forms of rabies encephalitis may exist, and 16 rabies survivors are known. Rabies should be considered earlier and more frequently in the diagnosis than current practice.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of rabies encephalitis includes all forms of severe cerebral infections, tetanus, and some intoxications and envenomations. Rabies can be confused with autoimmune (anti-N-methyl-D-aspartate receptor) encephalitis, other infectious encephalitis, psychiatric illness, drug abuse, and conversion disorders. Paralytic rabies is most frequently confused with Guillain-Barré syndrome. The diagnosis of rabies is frequently delayed in Western countries because of its rarity and the unfamiliarity of the medical staff with the infection. These considerations highlight the need to pursue a history of contact with an animal belonging to 1 of the known reservoirs for rabies or to establish a travel history to a rabies-endemic region.

**DIAGNOSIS**

The Centers for Disease Control and Prevention (CDC) require a number of tests to confirm a clinically suspected case of rabies. Reverse transcription polymerase chain reaction is the most sensitive available assay for the diagnosis of rabies when done iteratively. Rabies virus RNA has been detected in saliva, skin, and brain by the reverse transcription polymerase chain reaction. The virus can be grown both in cell culture and after animal injection, but identification of rabies by these methods is slow. Rabies antigen is detected through immunofluorescence of saliva or biopsies of hairy skin or brain. Corneal impressions are not recommended. Rabies-specific antibody can be detected in serum or CSF samples, but most patients die while seronegative. Antirabies antibodies are present in the sera of patients who have received an incomplete course of the rabies vaccine, precluding a meaningful interpretation in this setting. Antibody in CSF is rarely detected after vaccination and is considered diagnostic of rabies regardless of immunization status. CSF abnormalities in cell count, glucose, and protein content are minimal and are not diagnostic. MRI findings in the brain are late.

**TREATMENT AND PROGNOSIS**

Rabies is generally fatal. Conventional critical care yielded 1 survivor from 74 attempts since 1990. Five of 16 patients survived without use of critical care (including 3 milder cases) and 7 with use of the Milwaukee Protocol (http://www.mcw.edu/rabies). Survival using the Milwaukee Protocol is estimated at 20%; neurologic outcomes are poor in one third of patients. Neither rabies immunoglobulin (RIG) nor rabies vaccine provides benefit once symptoms have appeared. Among 11 survivors of rabies after use of biologics, 6 had poor neurologic outcomes. Among 5 vaccine-naive survivors, 1 had a poor outcome. Antiviral treatments have not been effective. Ribavirin delays the immune response and should be avoided during early management. In contrast, appearance of the normal antibody response by 7 days is associated with clearance of salivary viral load and survival.

**PREVENTION**

Primary prevention of rabies infection includes vaccination of domestic animals and education to avoid wild animals, stray animals, and animals with unusual behavior.

**Immunization and Fertility Control of Animal Reservoirs**

The introduction of routine rabies immunization for domestic pets in the United States and Europe during the middle of the 20th century virtually eliminated infection in dogs, which prior to that time had been the principal transmitter of rabies to humans in developed, as well as nonindustrialized, countries. In the 1990s, control efforts in Europe and North America shifted to immunization of wildlife reservoirs of rabies, where rabies was newly emerging. These programs employed bait laced with either an attenuated rabies vaccine or a recombinant rabies surface glycoprotein inserted into vaccinia, distributed by air or hand into areas inhabited by rabid animals. Human contact with vaccine-laden bait has been infrequent. Adverse events after such contact have been rare, but the vaccinia vector poses a threat to the same population at risk for vaccinia itself, namely, pregnant women, immunocompromised patients, and people with atopic dermatitis. Mass culling of endemic reservoirs has never worked; vaccination and fertility control stop outbreaks. Bats are ubiquitous and very important for insect control. Less than 1% of free-flying bats but >8% of downed bats and bats found in dwellings are rabid.

**Postexposure Prophylaxis**

The relevance of rabies for most pediatricians centers on evaluating whether an animal exposure warrants PEP (Table 274-1). No case of rabies has been documented in a person receiving the recommended schedule of PEP since introduction of modern cellular vaccines in the 1970s.

Given the incubation period for rabies, PEP is a medical urgency, not emergency. Algorithms have been devised to aid practitioners in deciding when to initiate rabies PEP (Fig. 274-1). The decision to proceed ultimately depends on the local epidemiology of animal rabies

1642  Part XVII  Infectious Diseases
as determined by active surveillance programs, information that can be obtained from local and state health departments. In general, bats, raccoons, skunks, coyotes, and foxes should be considered rabid unless proven otherwise through euthanasia and testing of brain tissue, whereas bites from small herbivorous animals (squirrels, hamsters, gerbils, chipmunks, rats, mice, and rabbits) can be discounted. The response to bites from a pet, particularly a dog, cat, or ferret, depends on local surveillance statistics and on whether the animal is available for observation.

The approach to nonbite bat exposures is controversial. In response to the observation that most cases of rabies in the United States have been caused by bat variants and that the majority of affected patients had no recollection of a bat bite, the CDC has recommended that rabies PEP be considered after any physical contact with bats and when a bat is found in the same room as persons who may not be able to accurately report a bite, assuming that the animal is unavailable for testing. Such people include young children, the mentally disabled, and intoxicated individuals. Other nonbite contacts (e.g., handling a carcass, exposure to an animal playing with a carcass, or coming into contact with blood or excreta from a potentially rabid animal) usually do not require PEP.

In all instances of a legitimate exposure, effort should be made to recover the animal for quarantine and observation or brain examination after euthanasia. Testing obviates the need for PEP more than half the time. In most instances, PEP can be deferred until the results of observation or brain histology are known. In dogs, cats, and ferrets, symptoms of rabies always occur within several days of viral shedding; therefore, in these animals a 10-day observation period is sufficient to eliminate the possibility of rabies.

No duration of time between exposure and onset of symptoms should preclude rabies prophylaxis. Rabies PEP is most effective when applied expeditiously. Nevertheless, the series should be initiated in the asymptomatic person as soon as possible, regardless of the length of time since the bite. The vaccine and RIG are contraindicated once symptoms develop.

The first step in rabies PEP is to cleanse the wound thoroughly. Soapy water is sufficient to inactivate an enveloped virus, and its effectiveness is supported by broad experience. Other commonly used

*During the 10-day observation period, at the first sign of rabies in the biting dog, cat, or ferret, treatment of the exposed person with RIG (human) and vaccine should be initiated. The animal should be euthanized immediately and tested.

†The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Immunization is discontinued if immunofluorescent test result for the animal is negative.

‡RIG, rabies immunoglobulin.

Disinfectants, such as iodine-containing preparations, are virucidal and should be used in addition to soap when available. Probably the most important aspect of this component is that the wound is cleansed with copious volumes of disinfectant. Primary closure is avoided; wounds may be bacterially infected as well, so cosmetic repair should follow. Antibiotics and tetanus prophylaxis (see Chapter 211) should be applied with the use of usual wound care criteria.

The second component of rabies PEP consists of passive immunization with RIG. Most failures of PEP are attributed to not using RIG. Human RIG, the formulation used in industrialized countries, is administered at a dose of 20 IU/kg. As much of the dose is infused around the wound as possible, and the remainder is injected intramuscularly in a limb distant from the one injected with the killed vaccine. Like other immunoglobulin preparations, RIG interferes with the take of live viral vaccines for at least 4 mo after administration of the RIG dose. Human RIG is not available in many parts of the developing world. Equine RIG serves as a substitute for the human immunoglobulin preparation in some areas. Modern preparations of equine RIG are associated with fewer side effects than prior products composed of crude horse serum. Regrettably, for a large segment of the world’s population, no passive immunization product is available at all. Monoclonal antibody products are in clinical trials and may alleviate this deficiency.

The third component of rabies PEP is immunization with inactivated vaccine. In most of the world, cell-based vaccines have replaced previous preparations. Two formulations currently are available in the United States, namely, RabAvert (Chiron Behring Vaccines, Maharashtra, India), a purified chick-embryo cell cultivated vaccine, and Imovax Rabies (Aventis Pasteur, Bridgewater, NJ), cultivated in human diploid cell cultures. In both children and adults, both vaccines are administered intramuscularly in a 1 mL volume in the deltoid or anterolateral thigh on days 0, 3, 7, and 14 after presentation. Injection into the gluteal area is associated with a blunted antibody response, so this area should not be used. The rabies vaccines can be safely administered during pregnancy. In most persons the vaccine is well tolerated; most adverse effects are related to booster doses. Pain and erythema at the injection site occur commonly, and local adenopathy, headache, and myalgias occur in 10-20% of patients. Approximately 5% of patients who receive the human diploid cell vaccine experience an immune complex–mediated allergic reaction, including rash, edema, and arthralgias, several days after a booster dose. The World Health Organization has approved schedules using smaller amounts of vaccine, administered intradermally, that are immunogenic and protective (http://www.who.int/rabies/human/postexp/en/), but none is approved for use in the United States. Other cell culture–derived rabies virus vaccines are available in the developing world. A few countries still produce nerve tissue–derived vaccines; these preparations are poorly immunogenic, and cross-reactivity with human nervous tissue may occur with their use, producing severe neurologic symptoms even in the absence of rabies infection.

Preexposure Prophylaxis

The killed rabies vaccine can be given to prevent rabies in persons at high risk for exposure to wild-type virus, including laboratory personnel working with rabies virus, veterinarians, and others likely to be exposed to rabid animals as part of their occupation. Preexposure prophylaxis should be considered for persons traveling to a rabies-endemic region where there is a credible risk for a bite or scratch from a rabies-infected animal, particularly if there is likely to be a shortage of RIG or cell culture–based vaccine (see Chapter 175). Rabies vaccine as part of the routine vaccine series is under investigation in some countries. The schedule for preexposure prophylaxis consists of 3 intramuscular injections on days 0, 7, and 21 or 28. PEP in the patient who has received preexposure prophylaxis or a prior full schedule of PEP consists of 2 doses of vaccine (1 each on days 0 and 3) and does not require RIG. Immunity from preexposure prophylaxis wanes after several years and requires boosting if the potential for exposure to rabid animals recurs.

Bibliography

The polyomaviruses are small (45 nm), nonenveloped, circular, double-stranded DNA viruses with genomes of approximately 5,000 bp. Because of the association of animal polyomaviruses with tumors in the animals they infect, there has also been concern for a relationship to neoplasia in humans; however, the only virus for which there is strong evidence for an etiologic role in neoplasia is Merkel cell polyomavirus (see below). Among the polyomaviruses, the traditional human pathogens are JC virus and BK viruses. In recent years the number of human polyomaviruses has expanded dramatically, with discovery in humans of 10 additional viruses. Two of the newer polyomaviruses, designated KI virus and WU virus, can be detected in respiratory samples from children; however, a pathogenic role for these viruses has not been proven to date. Merkel cell polyomavirus is associated with Merkel cell carcinoma, an unusual neuroectodermal tumor of the skin that occurs primarily in elderly and immunocompromised individuals. Clonal integration of Merkel cell polyomavirus DNA is present in Merkel cell carcinoma cells, supporting an etiologic role for the virus in the development of the tumor. Another human polyomavirus has been isolated from patients with the dermatologic condition trichodysplasia spinulosa and has been named trichodysplasia spinulosa–associated polyomavirus. Trichodysplasia spinulosa is a condition of the skin that occurs in immunocompromised individuals and involves the development of follicular papules and keratin spines, usually involving the face. Two other viruses, designated human polyomaviruses 6 and 7, have also been found in human skin samples, but are not presently known to cause disease. Human polyomavirus 9 was detected in serum from a renal transplant recipient. The most recently discovered viruses, named Malawi virus and St. Louis virus, were first detected in stool samples, but a role in gastrointestinal or other disease has not been established at this time.

JC and BK viruses are tropic for renal epithelium; JC virus also infects brain oligodendrocytes and is the etiologic agent of progressive multifocal leukoencephalopathy, a rare and fatal demyelinating disease of immunocompromised persons, especially those with AIDS. Progressive multifocal leukoencephalopathy is now known to occur in individuals receiving the immunomodulatory agents natalizumab (Tysabri), used to treat multiple sclerosis and Crohn disease, and efalizumab (Raptiva), used to treat psoriasis. It has also been reported in individuals receiving the anti-CD20 monoclonal antibody rituximab (Rituxan) and the anti-CD52 monoclonal antibody alemtuzumab (Campath). BK virus is the cause of transplant nephropathy in renal transplant recipients and of hemorrhagic cystitis in hematopoietic stem cell and bone marrow transplant recipients. Several million persons in the United States were exposed to simian virus 40 (SV40), an oncogenic polyomavirus of Asian macaques, from contaminated poliovirus vaccines administered during 1955-1963. There were no recognized sequelae and no demonstrable increased risk for cancer.

Seroepidemiologic studies have shown that infection with all of the human polyomaviruses appears to be widespread, often occurring during childhood. Primary infection with these viruses is not recognized clinically. Approximately half of children in the United States are infected with BK virus by 3-4 yr of age and with JC virus by 10-14 yr of age, and approximately 60-80% of adults are seropositive for 1 or both viruses. Infection with polyomaviruses is thought to persist throughout life, with JC and BK viruses remaining latent in renal epithelium, oligodendrocytes, and peripheral blood mononuclear cells. The site of latency of the other human polyomaviruses is not currently known. Approximately 30-50% of healthy persons have detectable BK or JC virus in renal tissue at autopsy. Reactivation and viruria occur...
with increased frequency with advancing age and are more common in immunocompromised persons. On the basis of polymerase chain reaction results, BK and JC viruria occur in 2.6% and 13.2%, respectively, of persons younger than 30 yr of age and in approximately 9% and 50%, respectively, of persons older than 60 yr of age.

 Reactivation of BK and JC viruses with asymptomatic viruria occurs in 10-50% of hematopoietic stem cell and bone marrow transplant recipients and in 30% of renal transplant recipients. Of those renal transplant recipients who demonstrate BK viruria, approximately one third also have plasma viremia. Recipients with plasma viremia are at risk for development of nephropathy, which can clinically mimic allograft rejection and can result in failure of the allograft. Reduction of immunosuppression has been effective in preventing progression from viremia to nephropathy, and thus posttransplantation monitoring of either urine or plasma by polymerase chain reaction is important. It is particularly important to distinguish BK nephropathy from rejection because the treatments are different—increase in immunosuppression for rejection but decrease in immunosuppression for BK nephropathy.

 Polymerase chain reaction is the preferred means to detect the BK and JC viruses. The high seroprevalence in the general population and lack of clear relationship to clinical illness limit the usefulness of serologic testing. There are no proven antiviral treatments for BK or JC virus infection, although cidofovir may be effective in some cases of BK-related transplant nephropathy. Effective treatment of AIDS with antiretroviral therapy can prevent the progression of progressive multifocal leukoencephalopathy.

Bibliography
diverse diseases in several animal species. The HIV-1 genome contains 2 copies of single-stranded RNA that is 9.2 kb in size. At both ends of the genome there are identical regions, called long terminal repeats, which contain the regulation and expression genes of HIV. The remainder of the genome includes 3 major sections: the GAG region, which encodes the viral core proteins (p24 [capsid protein: CA], p17 [matrix protein: MA], p9, and p6, which are derived from the precursor p55); the POL region, which encodes the viral enzymes (i.e., reverse transcriptase [p66], protease [p10], and integrase [p32]); and the ENV region, which encodes the viral envelope proteins (gp120 and gp41, which are derived from the precursor gp160). Other regulatory proteins, such as transactivator of transcription (tat: p14), regulator of virion (rev: p19), negative regulatory factor (nef: p27), viral protein r (vpr: p15), viral infectivity factor (vif: p23), viral protein u (vpu in HIV-1: P16), and viral protein x (vpx in HIV-2: P15) are involved in transactivation, viral messenger RNA expression, viral replication, induction of cell cycle arrest, promotion of nuclear import of viral reverse transcription complexes, downregulation of CD4 receptors and class I major histocompatibility complex, proviral DNA synthesis, and virus release and infectivity (Fig. 276-2).

The HIV tropism to the target cell is determined by its envelope glycoprotein (Env). Env consists of 2 components, namely the surface heavily glycosylated subunit gp120 protein and the associated transmembrane subunit glycoprotein gp41. Both gp120 and gp41 are produced from the precursor protein gp160. The glycoprotein gp41 is very immunogenic and is used to detect HIV-1 antibodies in diagnostic assays; gp120 is a complex molecule that includes the highly variable V3 loop. This region is immunodominant for neutralizing antibodies. The heterogeneity of gp120 presents major obstacles in establishing an effective HIV vaccine. The gp120 glycoprotein also carries the binding site for the CD4 molecule, the most common host cell surface receptor of T lymphocytes. This tropism for CD4+ T cells is beneficial to the virus because of the resulting reduction in the effectiveness of the host immune system. Other CD4-bearing cells include macrophages and microglial cells. The observations that CD4+ cells are also infected by HIV and that some CD4+ T cells are resistant to such infections suggests that other cellular attachment sites are needed for the interaction between HIV and human cells. Several chemokines serve as coreceptors for the envelope glycoproteins, permitting membrane fusion and entry into the cell. Most HIV strains have a specific tropism for 1 of the chemokines, including the fusion-inducing molecule CXCR-4, which acts as a coreceptor for HIV attachment to lymphocytes, and CCR-5, a β chemokine receptor that facilitates HIV entry into macrophages. Several other chemokine receptors (CCR-3) have also been shown in vitro to serve as virus co-receptors. Other mechanisms of attachment of HIV to cells use nonneutralizing antiviral antibodies and complement receptors. The Fab portion of these antibodies attaches to the virus surface, and the Fc portion binds to cells that express Fc receptors (macrophages, fibroblasts), thus facilitating virus transfer into the cell. Other cell-surface receptors, such as mannose-binding protein on macrophages or DC-specific C-type lectin (DC-SIGN) on dendritic cells, also bind to the HIV-1 envelope glycoprotein and increase the efficiency of viral infectivity. Cell-to-cell transfer of HIV without formation of fully formed particles is a more rapid mechanism of spreading the infection to new cells than is direct infection by the virus.

Following viral attachment, gp120 and the CD4 molecule undergo conformational changes, and gp41 interacts with the fusion receptor on the cell surface (Fig. 276-3). Viral fusion with the cell membrane allows entry of viral RNA into the cell cytoplasm. This process involves accessory viral proteins (nef, vif) and binding of cyclophilin A (a host cellular protein) to the capsid protein (p24). The p24 protein is involved in virus uncoating, recognition by restriction factors, and nuclear importation and integration of the newly created viral DNA. Viral DNA copies are then transcribed from the virion RNA through viral reverse transcriptase enzyme activity, which builds the 1st DNA strand from the viral RNA and then destroys the viral RNA and builds a 2nd DNA strand to produce double-stranded circular DNA. The HIV-1 reverse transcriptase is error prone and lacks error-correcting mechanisms. Thus, many mutations arise, creating wide genetic variation in...
antiprotease drugs have been developed, targeting the increased production of the viral RNA genome, which, in turn, leads to production in response to various external factors such as an increase in inflammatory cytokines (by infection with other pathogens) and cellular activation. Anti-HIV drugs that block the integrase enzyme activity have been developed. Depending on the relative expression of the viral regulatory genes (tat, rev, nef), the proviral DNA may encode production of the viral RNA genome, which, in turn, leads to production of viral proteins necessary for viral assembly.

HIV-1 transcription is followed by translation. A capsid polyprotein is cleaved to produce, the virus-specific protease (p10), among other products. This enzyme is critical for HIV-1 assembly because it cleaves the long polyproteins into the proper functional pieces. Several HIV-1 antiprotease drugs have been developed, targeting the increased sensitivity of the viral protease, which differs from the cellular proteases. The regulatory protein vif is active in virus assembly and Gag processing. The RNA genome is then incorporated into the newly formed viral capsid that requires zinc finger domains (p7) and the matrix protein (MA: p17). The matrix protein forms a coat on the inner surface of the viral membrane, which is essential for the budding of the new virus from the host cell's surface. As new virus is formed, it buds through specialized membrane areas, known as lipid rafts, and is released. The virus release is facilitated by the viroporin vpu, which induces rapid degradation of newly synthesized CD4 molecules that impede viral budding. In addition, vpu counteracts host innate immunity (e.g., hampering natural killer T-cell activity).

Full-length sequencing of the HIV-1 genome demonstrated 3 different groups (M [main], O [outlier], and N [non-M, non-O]), probably occurring from multiple zoonotic infections from primates in different geographic regions. The same technique identified 8 groups of HIV-2 isolates. Group M diversified to 9 subtypes (or clades A to D, F to H, J and K). In each region of the world, certain clades predominate, for example, clade A in Central Africa, clade B in the United States and South America, clade C in South Africa, clade E in Thailand, and clade F in Brazil. Although some subtypes were identified within group O, none was found in any of the HIV-2 groups. Clades are mixed in some patients as a result of HIV recombination, and some crossing between groups (i.e., M and O) has been reported.

HIV-2 has a similar life cycle to HIV-1 and is known to cause infection in several monkey species. Subtypes A and B are the major causes of infection in humans, but rarely cause infection in children. HIV-2 differs from HIV-1 in its accessory genes (e.g., it has no vpu gene but contains the vpx gene, which is not found in HIV-1). It is most prevalent in western Africa, but increasing numbers of cases are reported from Europe and southern Asia. The diagnosis of HIV-2 infection is more difficult because of major differences in the genetic sequences between HIV-1 and HIV-2. Thus, several of the standard confirmatory assays (immunoblot), which are HIV-1 specific, may give indeterminate results with HIV-2 infection. If HIV-2 infection is suspected, a combination screening test that detects antibody to HIV-1 and HIV-2 peptides should be used. In addition, the rapid HIV detection tests have been less reliable in patients suspected to be dually infected with HIV-1 and HIV-2, because of lower antibody concentrations against HIV-2.

**EPIDEMIOLOGY**

The World Health Organization (WHO) estimated that in 2013, 3.2 million children younger than 15 yr of age worldwide were living with...
Acquired Immunodeficiency Syndrome (Human Immunodeficiency Virus)

occurred in young males who have sex with males (MSM), with a 48% increase in new infections in black MSM between 2006 and 2009. More than 50% of HIV-positive youth report being unaware of their diagnosis. Considering the long latency period between the time of infection and the development of clinical symptoms, reliance on AIDS case definition surveillance data significantly underrepresents the impact of the disease in adolescents. Based on a median incubation period of 8-12 yr, it is estimated that 15-20% of all AIDS cases were acquired between 13 and 19 yr of age.

Risk factors for HIV infection vary by gender in adolescents. For example, 91-93% of males between the ages of 13 and 24 yr with HIV acquire infection through sex with males. In contrast, 91-93% of adolescent females with HIV are infected through heterosexual contact. As in the pediatric population, adolescent racial and ethnic minority populations are overrepresented, especially among females.

Transmission of HIV-1 occurs via sexual contact, parenteral exposure to blood, or vertical transmission from mother to child. The primary route of infection in the pediatric population is vertical transmission. Rates of transmission of HIV from mother to child have varied in high- and low-resource countries; the United States and Europe have documented transmission rates in untreated women between 12% and 30%, whereas transmission rates in Africa and Haiti have been higher (25-52%), likely because of more advanced maternal disease and the presence of coinfections. Perinatal treatment of HIV-infected pregnant women with antiretroviral drugs has dramatically decreased the rate to <2%.
Vertical transmission of HIV can occur before (intrauterine), during (intrapartum), or after delivery (through breastfeeding). Although intrauterine transmission has been suggested by identification of HIV by culture or polymerase chain reaction (PCR) in fetal tissue as early as 10 wk, statistical modeling data suggest that the majority of in utero transmissions likely occur in late gestation, when the vascular integrity of the placenta weakens and microtransfusions across the maternal–fetal circulation occur. It is generally accepted that 20-30% of infected newborns are infected in utero, because this percentage of infants has laboratory evidence of infection (positive maternal culture or PCR) within the 1st wk of life. Some studies have found that viral detection soon after birth also correlates with early onset of symptoms and rapid progression to AIDS, consistent with more long-standing infection during gestation.

A higher percentage of HIV-infected children acquire the virus in utero, evidenced by the fact that 70-80% of infected infants do not demonstrate detectable virus until after 1 wk of age. The mechanism of transmission appears to be mucosal exposure to infected blood and cervicovaginal secretions in the birth canal, and intrauterine contractions during active labor/delivery could also increase the risk of late microtransfusions. Breastfeeding is the least-common route of vertical transmission in industrialized nations, but is responsible for as much as 40% of perinatal infections in resource-limited countries. Both free and cell-associated viruses have been detected in breast milk from HIV-infected mothers. The risk for transmission through breastfeeding is approximately 9-16% in women with established infection, but is 29-53% in women who acquire HIV postnatally, suggesting that the viremia experienced by the mother during primary infection at least triples the risk for transmission. Where replacement feeding is readily available and safe, it seems reasonable for women to substitute infant formula for breast milk if they are known to be HIV infected or are at risk for ongoing sexual or parenteral exposure to HIV. However, the WHO recommends that in low-resource countries where other diseases (diarrhea, pneumonia, malnutrition) substantially contribute to a high infant mortality rate, the benefit of breastfeeding outweighs the risk for HIV transmission, and HIV-infected women in developing countries should breastfeed their infants for at least the 1st 6 mo of life (see “Prevention” below).

Several risk factors influence the rate of vertical transmission: maternal viral load at delivery, perterm delivery (<34 wk gestation), and low maternal antenatal CD4 count. The most important variable appears to be the level of maternal viremia; the odds of transmission may be <1,000 copies/mL. It should be noted that rarely (<0.1%) transmission may occur with maternal viral loads <50 copies/mL.

Transfusions of infected blood or blood products have accounted for 3-6% of all pediatric AIDS cases. The period of highest risk was between 1978 and 1985, before the availability of HIV antibody-screened blood products. Whereas the prevalence of HIV infection in individuals with hemophilia treated before 1985 was as high as 70%, heat treatment of factor VIII concentrate and HIV antibody screening of donors has virtually eliminated HIV transmission in this population. Donor screening has dramatically reduced, but not eliminated, the risk for blood transfusion–associated HIV infection: nucleic acid amplification testing of “minipools” (pools of 16-24 donations) performed on antibody-negative blood donations (to identify donations made during the window period before seroconversion) reduced the residual risk of transfusion-transmitted HIV-1 to approximately 1 in 2 million blood units. However, in many resource-limited countries, screening of blood is not uniform, and the risk for transmitting HIV infection via transfusion remains.

Although HIV can be isolated rarely from saliva, it is in very low titers (<1 infectious particle/mL) and has not been implicated as a transmission vehicle. Studies of hundreds of household contacts of HIV-infected individuals have found that the risk for household HIV transmission is practically nonexistent. Only a few cases have been reported in which urine or feces (possibly devoid of visible blood) have been proposed as a possible vehicle of HIV transmission.

In the pediatric population, sexual transmission is infrequent, but a small number of cases resulting from sexual abuse have been reported. Sexual contact is a major route of transmission in the adolescent population, accounting for most of the cases.

**PATHOGENESIS**

HIV infection affects most of the immune system and disrupts its homeostasis (see Fig. 276-3). In most cases, the initial infection is caused by low amounts of a single virus. Therefore, disease may be prevented by prophylactic drug(s) or vaccine. When the mucosa serves as the portal of entry for HIV, the 1st cells to be affected are the dendritic cells. These cells collect and process antigens introduced from the periphery and transport them to the lymphoid tissue. HIV does not infect the dendritic cell but binds to its DC-SIGN surface molecule, allowing the virus to survive until it reaches the lymphatic tissue. In the lymphatic tissue (e.g., lamina propria, lymph nodes), the virus selectively binds to cells expressing CD4 molecules on their surface, primarily helper T lymphocytes (CD4+ T cells) and cells of the monocyte-macrophage lineage. Other cells bearing CD4, such as microglia, astrocytes, oligodendroglia, and placental tissue containing villous Hofbauer cells, may also be infected by HIV. Additional factors (coreceptors) are necessary for HIV fusion and entry into cells. These factors include the chemokines CXCR4 (fusion) and CCR5. Other chemokines (CCR1, CCR3) may be necessary for the fusion of certain HIV strains. Several host genetic determinants affect the susceptibility to HIV infection, the progression of disease, and the response to treatment. These genetic variants vary in different populations. A deletion in the CCR5 gene that is protective against HIV infection (CCR5Δ32) is relatively common in whites but is rare in blacks. Several other genes that regulate chemokine receptors, ligands, the histocompatibility complex, and cytokines also influence the outcome of HIV infection. Usually, CD4+ lymphocytes migrate to the lymphatic tissue in response to viral antigens and then become activated and proliferate, making them highly susceptible to HIV infection. This antigen-driven migration and accumulation of CD4 cells within the lymphoid tissue may contribute to the generalized lymphadenopathy characteristic of the acute retroviral syndrome in adults and adolescents. HIV preferentially infects the very cells that respond to it (HIV-specific memory CD4+ T cells) and cells of the monocyte-macrophage lineage, accounting for most of the cases. Sexual contact is a major route of transmission in the adolescent population, accounting for most of the cases. The HIV rapidly responds to the immune system pressure by developing a genetically complex population (quasispecies) that successfully evade it. In addition, inappropriate use of antiretroviral treatment increases the ability of the virus to diverge even further. Early HIV-1 replication in children has no apparent clinical manifestations. Whether tested by virus isolation or by PCR for viral nucleic acid sequences, fewer than 40% of HIV–infected infants demonstrate evidence of the virus at birth. The virus load increases by 1-4 mo, and almost all HIV-infected infants have detectable HIV-1 in peripheral blood by 4 mo of age.

In adults, the long period of clinical latency (8-12 yr) is not indicative of viral latency. In fact, there is a very high turnover of virus and CD4 lymphocytes (more than a billion cells per day), gradually causing deterioration of the immune system, marked by depletion of CD4 cells.
Several mechanisms for the depletion of CD4 cells in adults and children have been suggested, including HIV-mediated single cell killing, formation of multinucleated giant cells of infected and uninfected CD4 cells (syncytia formation), virus-specific immune responses (natural killer cells, antibody-dependent cellular cytotoxicity), superantigen-mediated activation of T cells (rendering them more susceptible to infection with HIV), autoimmunity, and programmed cell death (apoptosis). The viral burden is greater in the lymphoid organs than in the peripheral blood during the asymptomatic period. As HIV virions and their immune complexes migrate through the lymph nodes, they are trapped in the network of dendritic follicular cells. Because the ability of HIV to replicate in T cells depends on the state of activation of the cells, the immune activation that takes place within the microenvironment of the lymph nodes in HIV disease serves to promote infection of new CD4 cells as well as subsequent viral replication within these cells. Monocytes and macrophages can be productively infected by HIV yet resist the cytopathic effect of the virus and, with their long lifespan, explain their role as reservoirs of HIV and as effectors of tissue damage in organs such as the brain. In addition, they reside in anatomic viral sanctuaries where current treatment agents are less effective.

The innate immune system responds almost immediately following HIV infection by recognizing the viral nucleic acids, once the virus fuses into the infected cell, by the toll-like receptor 7. This engagement leads to activation of proinflammatory cytokines and interferon (IFN-α), which blocks virus replication and spread. The virus uses its Nef protein to downregulate the expression of major histocompatibility complex (MHC) and non-MHC ligands to reduce the natural killing (NK) cell–mediated anti-HIV activity. It also modulates NK cell differentiation and maturation, dysregulates cytokine production, and increases apoptosis. While the mechanism by which the innate system triggers the adaptive immune response is not yet fully understood, cell-mediated and humoral responses occur early in the infection. CD8 T cells play an important role in containing the infection. These cells produce various ligands (macrophage inflammatory proteins 1α and 1β, RANTES), which suppress HIV replication by blocking the binding of the virus to the coreceptors (CCR5). HIV-specific cytotoxic T lymphocytes (CTLs) develop against both the structural (ENV, POL, GAG) and regulatory (tat) viral proteins. The CTLs appear at the end of the acute infection, as viral replication is controlled by killing HIV-infected cells before new viruses are produced and by secreting potent antiviral factors that compete with the virus for its receptors (CCR5). Neutralizing antibodies appear later in the infection and seem to help in the continued suppression of viral replication during clinical latency. There are at least 2 possible mechanisms that control the steady-state viral load level during the chronic clinical latency. One mechanism may be the limited availability of activated CD4 cells, which prevent further increase in viral load. The other mechanism is development of an active immune response, which is influenced by the amount of viral antigen and limits viral replication at a steady state. There is no general consensus about which of these 2 mechanisms is more important. The CD4 cell limitation mechanism accounts for the effect of antiretroviral therapy, whereas the immune response mechanism emphasizes the importance of immune modulation treatment (cytokines, vaccines) to increase the efficiency of immune-mediated control. A group of cytokines that includes tumor necrosis factor TNF-α, TNF-β, interleukin IL-1, IL-2, IL-3, IL-6, IL-8, IL-12, IL-15, granulocyte–macrophage colony-stimulating factor, and macrophage colony-stimulating factor plays an integral role in upregulating HIV expression from a state of quiescent infection to active viral replication. Other cytokines such as IFN-γ, IFN-β, and IL-13 exert a suppressive effect on HIV replication. Certain cytokines (IL-4, IL-10, IFN-γ, transforming growth factor–β) reduce or enhance viral replication depending on the infected cell type. The interactions among these cytokines influence the concentration of viral particles in the tissues. Plasma concentrations of cytokines need not be elevated for them to exert their effect, because they are produced and act locally in the tissues. The activation of virtually all the cellular components of the immune system (i.e., T and B cells, natural killer cells, and monocytes) plays a significant role in the pathologic aspects of HIV infection. Further understanding of their interactions during the infection will expand our treatment options. Commonly, HIV isolated during the clinical latency period grows slowly in culture and produces low titers of reverse transcriptase. These isolates use CCR5 as their coreceptor. By the late stages of clinical latency, the isolated virus is phenotypically different. It grows rapidly and to high titers in culture and uses CXCR4 as its coreceptor. The switch from CCR5 receptor to CXCR4 receptor increases the capacity of the virus to replicate, to infect a broader range of target cells (CXCR4 is more widely expressed on resting and activated immune cells), and to kill T cells more rapidly and efficiently. As a result, the clinical latency phase is over and progression toward AIDS is noted. The progression of disease is related temporally to the gradual disruption of lymph node architecture and degeneration of the follicular dendritic cell network with loss of its ability to trap HIV particles. The virus is freed to recirculate, producing high levels of viremia and an increased disappearance of CD4 T cells during the later stages of disease.

The clinical course of the HIV infection shows a substantial heterogeneity. This variation is determined by both viral and host factors. HIV viruses that use coreceptor CXCR4 in the course of the infection are associated with an accelerated deterioration of the immune system and more rapid progression to AIDS. In addition, several host genetic determinants (e.g., variants in the human leukocyte antigen region, polymorphisms in the CCR5 region like CCR5Δ32) were already identified as affecting the disease course. Three distinct patterns of disease were described in children. Approximately 15-25% of HIV-infected newborns in developed countries present with a rapid disease course, with onset of AIDS and symptoms during the 1st few months of life and a median survival time of 6-9 mo if untreated. In resource-poor countries, the majority of HIV-infected newborns will have this rapidly progressing disease. It has been suggested that if intrauterine infection coincides with the period of rapid expansion of CD4 cells in the fetus, the virus could effectively infect the majority of the body’s immunocompetent cells. The normal migration of these cells to the marrow, spleen, and thymus would result in efficient systemic delivery of HIV, unchecked by the immature immune system of the fetus. Thus, infection would be established before the normal ontogenic development of the immune system, causing more-severe impairment of immunity. Most children in this group have a positive HIV-1 culture and/or detectable virus in the plasma (median level: 11,000 copies/mL) in the 1st 48 hr of life. This early evidence of viral presence suggests that the newborn was infected in utero. The viral load rapidly increases, peaking by 2-3 mo of age (median: 750,000 copies/mL) and staying high for at least the 1st 2 yr of life.

From 60-80% of perinatally infected newborns in developed countries present with a much slower progression of disease, with a median survival time of 6 yr representing the 2nd pattern of disease. Many patients in this group have a negative viral culture or PCR in the 1st wk of life and are therefore considered to be infected intrapartum. In a typical patient, the viral load rapidly increases, peaking by 2-3 mo of age (median: 100,000 copies/mL) and then slowly declines over a period of 24 mo. The slow decline in viral load is in sharp contrast to the rapid decline after primary infection seen in adults. This observation can be explained only partially by the immaturity of the immune system in newborns and infants.

The 3rd pattern of disease occurs in <5% of perinatally infected children, referred to as long-term survivors, who have minimal or no progression of disease with relatively normal CD4 counts and very low viral loads for longer than 8 yr. Mechanisms for the delay in disease progression include effective humoral immunity and/or CTL responses, host genetic factors (e.g., human leukocyte antigen profile), and infection with attenuated (defective gene) virus. A subgroup of the long-term survivors called “elite survivors” has no detectable viruses in the blood and may reflect different or greater mechanisms of protection from disease progression.

HIV-infected children have changes in the immune system that are similar to those in HIV-infected adults. CD4 cell depletion may be less dramatic because infants normally have a relative lymphocytosis. A value of 1,500 CD4 cells/μL in children younger than 1 yr of age is indicative of severe CD4 depletion and is comparable to <200 CD4
cells/µL in adults. Lymphopenia is relatively rare in perinatally infected children and is usually only seen in older children or those with end-stage disease. Although cutaneous anergy is common during HIV infection, it is also frequent in healthy children younger than 1 yr of age, and thus its interpretation is difficult in infected infants. The depletion of CD4 cells also decreases the response to soluble antigens such as in vitro mitogens phytohemagglutinin and concanavalin A.

Polyclonal activation of B cells occurs in most children early in the infection, as evidenced by elevation of immunoglobulin (Ig) A, IgM, IgG, and particularly IgG (hypogammaglobulinemia), with high levels of anti-HIV-1 antibody. This response may reflect both dysregulation of T-cell suppression of B-cell antibody synthesis and active CD4 enhancement of B-lymphocyte humoral response. As a result, antibody response to routine childhood vaccinations may be abnormal. The B-cell dysregulation precedes the CD4 depletion in many children, and may serve as a surrogate marker of HIV infection in symptomatic children in whom specific diagnostic tests (PCR, culture) are not available or are too expensive. Despite the increased levels of immunoglobulins, some children lack specific antibodies or protective antibodies. Hypogammaglobulinemia is very rare (<1%).

Central nervous system (CNS) involvement is more common in pediatric patients than in adults. Macrophages and microglia play an important role in HIV neuropathogenesis, and data suggest that astrocytes may also be involved. Although the specific mechanisms for encephalopathy in children are not yet clear, the developing brain in young infants is affected by at least 2 mechanisms. The virus itself may directly infect various brain cells or cause indirect damage to the nervous system by the release of cytokines (IL-1β, TNF-α, IL-2) or reactive oxygen from HIV-infected lymphocytes or macrophages.

Appropriate therapy with antiretroviral agents may result in immune reconstitution inflammatory syndrome (IRIS), which is characterized by an increased inflammatory response from the recovered immune system to subclinical opportunistic infections (e.g., Mycobacterium, herpes simplex virus [HSV] infection, toxoplasmosis, cytomegalovirus [CMV] infection, Pneumocystis, cryptococcal infection). This condition is more commonly observed in patients with progressive disease and severe CD4+ T-lymphocyte depletion. Patients with IRIS develop fever and worsening of the clinical manifestations of the opportunistic infection or new manifestations (e.g., enlargement of lymph nodes, pulmonary infiltrates), typically within the 1st few weeks after initiation of antiretroviral therapy. Determining whether the symptoms represent IRIS, worsening of a current infection, a new opportunistic infection, or drug toxicity is often very difficult. If the syndrome does represent IRIS, adding nonsteroidal antiinflammatory agents or corticosteroids may alleviate the inflammatory reaction, although the use of corticosteroids is controversial. The inflammation may take weeks or months to subside. In most cases, continuation of anti-HIV treatment while treating the opportunistic infection (with or without antiinflammatory agents) is sufficient. If opportunistic infection is suspected prior to initiation of antiretroviral therapy, appropriate antimicrobial treatment should be given 1st.

### Clinical Manifestations

The clinical manifestations of HIV infection vary widely among infants, children, and adolescents. In most infants, physical examination at birth is normal. Initial symptoms may be subtle, such as lymphadenopathy and hepatosplenomegaly, or nonspecific, such as failure to thrive, chronic or recurrent diarrhea, respiratory symptoms, or oral thrush and may be distinguishable only by their persistence. Whereas systemic and pulmonary findings are common in the United States and Europe, chronic diarrhea, pneumonia, wasting, and severe malnutrition predominate in Africa. Clinical manifestations found more commonly in children than adults with HIV infection include recurrent bacterial infections, chronic parotid swelling, lymphocytic interstitial pneumonitis (LIP), and early onset of progressive neurological deterioration.

The CDC Surveillance Case Definition for HIV infection was revised in 2014 and has consolidated the staging system for children with adolescents and adults. It is based on age-specific CD4+ T-lymphocyte count or CD4+ T-lymphocyte percentage of total lymphocytes (Table 276-1), except when a stage 3-defining opportunistic illness (Table 276-2) supersedes the CD4 data. Age adjustment of the absolute CD4 count is necessary because counts that are relatively high in normal infants decline steadily until age 6 yr, when they reach adult norms. The CD4 count takes precedence over the CD4 T-lymphocyte percentage, and the percentage is considered only if the count is missing.

### Infections

Approximately 20% of AIDS-defining illnesses in children are recurrent bacterial infections caused primarily by encapsulated organisms such as Streptococcus pneumoniae and Salmonella as a result of disturbances in humoral immunity. Other pathogens, including Staphylococcus, Enterococcus, Pseudomonas aeruginosa, Haemophilus influenzae, and other Gram-positive and Gram-negative organisms, may also be seen. The most common serious infections in HIV-infected children are bacteremia, sepsis, and bacterial pneumonia, accounting for more than 50% of infections in these patients. Meningitis, urinary tract infections, deep-seated abscesses, and bone/joint infections occur less frequently. Milder recurrent infections, such as otitis media, sinusitis, and skin and soft tissue infections, are very common and may be chronic with atypical presentations.

Opportunistic infections are generally seen in children with severe depression of the CD4 count. In adults, these infections usually represent reactivation of a latent infection acquired early in life. In contrast, young children generally have primary infection and often have a more fulminating course of disease reflecting the lack of prior immunity. This principle is best illustrated by Pneumocystis jiroveci (formerly Pneumocystis carinii) pneumonia, the most common opportunistic infection in the pediatric population (see Chapter 244). The peak incidence of Pneumocystis pneumonia occurs at age 3-6 mo in the setting of undiagnosed perinatally acquired disease, with the highest mortality rate in children younger than 1 yr of age. Aggressive approaches to treatment have improved the outcome substantially. While the overall

---

| Table 276-1 | HIV Infection Stage* Based on Age-Specific CD4+ T-Lymphocyte Count or CD4+ T-Lymphocyte Percentage of Total Lymphocytes |
|---|---|---|---|
| **Age on Date of CD4+ T-Lymphocyte Test** | **<1 Yr** | **1-5 Yr** | **≥6 Yr** |
| **CD4+ T-Lymphocyte Count** | **CD4+ T-Lymphocyte Percentage** |
| **(cells/µL)** | **%** | **(cells/µL)** | **%** | **(cells/µL)** | **%** |
| 1 | ≥750 | ≥34 | ≥1,500 | ≥30 | ≥1,000 | ≥26 |
| 2 | 750-1,499 | 26-33 | 500-999 | 22-29 | 200-499 | 14-25 |
| 3 | <750 | <26 | <500 | <22 | <200 | <14 |

*Stage is based primarily on the CD4+ T-lymphocyte count. The CD4+ T-lymphocyte count takes precedence over the CD4+ T-lymphocyte percentage, and the percentage is considered only if the count is missing.

Table 276-2 Stage 3—Defining Opportunistic Illnesses in HIV Infection

| Bacterial infections, multiple or recurrent* | Candidiasis of bronchi, trachea, or lungs | Candidiasis of esophagus | Cervical cancer, invasive† | Coccidioidomycosis, disseminated or extrapulmonary | Cryptococcosis, extrapulmonary | Cryptosporidiosis, chronic intestinal (>1 mo duration) | Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 mo | Cytomegalovirus retinitis (with loss of vision) | Encephalopathy attributed to HIV† | Herpes simplex: chronic ulcers (>1 mo duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 mo) | Histoplasmosis, disseminated or extrapulmonary | Isosporiasis, chronic intestinal (>1 mo duration) | Kaposi sarcoma | Lymphoma, Burkitt (or equivalent term) | Lymphoma, immunoblastic (or equivalent term) | Lymphoma, primary, of brain | Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary | Mycobacterium tuberculosis of any site, pulmonary,† disseminated, or extrapulmonary | Mycobacterium, other species or unidentified species, disseminated or extrapulmonary | Pneumocystis jiroveci (previously known as Pneumocystis carinii) pneumonia | Pneumonia, recurrent† | Progressive multifocal leukoencephalopathy | Salmonella typhimurium, recurrent | Toxoplasmosis of brain, onset at age >1 mo | Wasting syndrome attributed to HIV† |
|---------------------------------------------|-----------------------------------------|-------------------------|---------------------------|---------------------------------|-----------------------------|-----------------------------|------------------------------------------------|----------------------------------|-------------------------------------------|------------------------------------------------|--------------------------------|-----------------------------|--------------------------------|-----------------------------|---------------------------------|--------------------------------|---------------------------------|--------------------------------|--------------------------------|--------------------------------|--------------------------------|-----------------------------|--------------------------------|
| *Only among children aged <6 yr. | †Only among adults, adolescents, and children aged ≥6 yr. | Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references: Centers for Disease Control and Prevention: 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR 43(No. RR-12), 1994. Centers for Disease Control and Prevention: 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 41(No. RR-17), 1992. | From Centers for Disease Control and Prevention: Revised surveillance case definition for HIV infection—United States, 2014. MMWR 63(No RR-3):1-10, 2014. |

incidence of opportunistic infections has markedly declined since the era of combination antiretroviral therapy, opportunistic infections still occur in patients with severe immunodeficiency as the result of unchecked viral replication, which often accompanies poor antiretroviral therapy adherence.

The classic clinical presentation of Pneumocystis pneumonia includes acute onset of fever, tachypnea, dyspnea, and marked hypoxemia; in some children, more indolent development of hypoxemia may precede other clinical or x-ray manifestations. Chest x-ray findings most commonly consist of interstitial infiltrates or diffuse alveolar disease, which rapidly progresses. Nodular lesions, streaky or lobar infiltrates, or pleural effusions may occasionally be seen. Diagnosis is established by demonstration of P. jiroveci with appropriate staining of induced sputum or bronchoalveolar fluid lavage; rarely, an open lung biopsy is necessary.

The 1st-line therapy for Pneumocystis pneumonia is intravenous trimethoprim-sulfamethoxazole (TMP-SMZ) (15-20 mg/kg/day of the TMP component every 6 hr IV) with adjunctive corticosteroids if the PaO2 is <70 mm Hg while breathing room air. When the patient has improved, therapy with oral TMP-SMZ should be continued for a total of 21 days while the corticosteroids are weaned. Alternative therapy for Pneumocystis pneumonia includes intravenous administration of pentamidine (4 mg/kg/day). Other regimens such as TMP plus dapsone, clindamycin plus primaquine, or atovaquone are used as alternatives in adults but have not been widely used in children to date.

**Nontuberculous mycobacterial infection**, with *Mycobacterium avium-intracellulare* complex (MAC), may cause disseminated disease in HIV-infected children who are severely immunosuppressed. The incidence of MAC infection in antiretroviral therapy-naive children with <100 CD4 cells/mm3 is estimated to be as high as 10%, but effective cART that results in viral suppression makes MAC infections rare. Disseminated MAC infection is characterized by fever, malaise, weight loss, and night sweats; diarrhea, abdominal pain, anorexia, intestinal perforation or jaundice (a result of biliary tract obstruction by lymphadenopathy) may also be present. Diagnosis is made by isolation of MAC from blood, bone marrow, or tissue; the isolated presence of MAC in the stool does not confirm a diagnosis of disseminated MAC. Treatment can reduce symptoms and prolong life but is at best only capable of suppressing the infection if severe CD4 depletion persists. Therapy should include at least 2 drugs: clarithromycin or azithromycin and ethambutol. A 3rd drug (rifabutin, rifampin, ciprofloxacin, levofloxacin, or amikacin) is generally added to decrease the emergence of drug-resistant isolates. Careful consideration of possible drug interactions with antiretroviral agents is necessary before initiation of disseminated MAC therapy. Drug susceptibilities should be ascertained, and the treatment regimen should be adjusted accordingly in the event of inadequate clinical response to therapy. Because of the great potential for toxicity with many of these medications, surveillance for adverse effects should be ongoing.

Oral candidiasis is the most common **fungal infection** seen in HIV-infected children. Oral nystatin suspension (2-5 mL qid) is often effective. Clotrimazole troches or fluconazole (3-6 mg/kg PO qd) are an effective alternative. Oral thrush progresses to involve the esophagus in as many as 20% of children with severe CD4 depletion, presenting with symptoms such as anorexia, dysphagia, vomiting, and fever. Treatment with oral fluconazole for 7-14 days generally results in rapid improvement in symptoms. Fungemia rarely occurs, usually in the setting of indwelling venous catheters, and up to 50% of cases may be caused by non–albicans species. Disseminated histoplasmosis, coccidioidomycosis, and cryptococcosis are rare in pediatric patients but may occur in endemic areas. Parasitic infections such as intestinal cryptosporidiosis and microsporidiosis and rarely isosporiasis or giardiasis are other opportunistic infections that cause significant morbidity. Although intestinal infections are usually self-limiting in healthy hosts, they cause severe chronic diarrhea in HIV-infected children with low CD4 counts, often leading to malnutrition. Nitazoxanide therapy is partially effective at improving cryptosporidiosis diarrhea, but immune reconstitution with cART is the most important factor for clearance of the infection. Albendazole has been reported to be effective against some microsporidia, and TMP-SMZ appears to be effective for isosporiasis.

**Viral infections**, especially with the herpesvirus group, pose significant problems for HIV-infected children. HSV causes recurrent gingivostomatitis, which may be complicated by local and distant cutaneous dissemination. Primary varicella-zoster virus infection (chickenpox) may be prolonged and complicated by bacterial infections or visceral dissemination, including pneumonitis. Recurrent, atypical, or chronic episodes of herpes zoster are often debilitating and require prolonged therapy with acyclovir; in rare instances, varicella-zoster virus has developed resistance to acyclovir, requiring the use of foscarnet. Disseminated CMV infection occurs in the setting of severe CD4 depletion (<50 CD4 cells/µL) and may involve single or multiple organs. Retinitis, pneumonitis, esophagitis, gastritis with pyloric obstruction, hepatitis, colitis, and encephalitis have been reported, but these complications are rarely seen if cART is given. Ganciclovir (6 mg/kg bid IV) and foscarnet (60 mg/kg tid IV) are the drugs of choice and are often given together in children with sight-threatening CMV retinitis. Intracerebral injections of foscarnet or intraocular ganciclovir implants plus oral valganciclovir have also been efficacious in adults and older children with CMV retinitis. Measles may occur despite immunization and may present without the typical rash. It often disseminates to the lung or brain with a high mortality rate.
Respiratory viruses such as respiratory syncytial virus and adenovirus may present with prolonged symptoms and persistent viral shedding. In parallel with the increased prevalence of genital tract human papillomavirus infection, cervical intraepithelial neoplasia and anal intraepithelial neoplasia also occur with increased frequency among HIV-1-infected adult women compared with HIV-seronegative women. The relative risk for cervical intraepithelial neoplasia is 5-10 times higher for HIV-1 seropositive women. Multiple modalities are used to treat human papillomavirus infection (see Chapter 266), although none is uniformly effective and the recurrence rate is high among HIV-1-infected persons.

Central Nervous System
The incidence of CNS involvement in perinatally infected children is as high as 50-90% in resource-limited countries but significantly lower in developed countries, with a median onset at 19 mo of age. Manifestations may range from subtle developmental delay to progressive encephalopathy with loss or plateau of developmental milestones, cognitive deterioration, impaired brain growth resulting in acquired microcephaly, and symmetric motor dysfunction. Encephalopathy may be the initial manifestation of the disease or may present much later when severe immune suppression occurs. With progression, marked apathy, spasticity, hyperreflexia, and gait disturbance may occur, as well as loss of language and oral, fine, and/or gross motor skills. The encephalopathy may progress intermittently, with periods of deterioration followed by transiently stable plateaus. Older children may exhibit behavioral problems and learning disabilities. Associated abnormalities identified by neuroimaging techniques include cerebral atrophy in up to 85% of children with neurologic symptoms, increased ventricular size, basal ganglia calcifications, and, less frequently, leukomalacia.

Fortunately, since the advent of cART, the incident rate of encephalopathy has dramatically declined to as low as 0.08% in 2006. However, as HIV-infected children progress through adolescence and young adulthood, other subtle manifestations of CNS disease are evident, such as cognitive deficits, attention problems, and psychiatric disorders. Living with a chronic, often stigmatizing, disease, parental loss, such as cognitive deficits, attention problems, and psychiatric disorders. The encephalopathy may progress intermittently, with periods of deterioration followed by transiently stable plateaus. Older children may exhibit behavioral problems and learning disabilities. Associated abnormalities identified by neuroimaging techniques include cerebral atrophy in up to 85% of children with neurologic symptoms, increased ventricular size, basal ganglia calcifications, and, less frequently, leukomalacia.

Focal neurologic signs and seizures are unusual and may imply a comorbid pathologic process such as a CNS tumor, opportunistic infection, or stroke. CNS lymphoma may present with new onset focal neurologic findings, headache, seizures, and mental status changes. Characteristic findings on neuroimaging studies include a hyperdense or isodense mass with variable contrast enhancement or a diffusely infiltrating contrast-enhancing mass. CNS toxoplasmosis is exceedingly rare in young infants, but may occur in HIV-infected adolescents and is typically associated with serum antitoxoplasma IgG as a marker of infection. Other opportunistic infections of the CNS are rare and include infection with CMV, JC virus (progressive multifocal leukoencephalopathy), HSV, Cryptococcus neoformans, and Coccidioides immittis. Although the true incidence of cerebrovascular disorders (both hemorrhagic and nonhemorrhagic strokes) is unclear, 6-10% of children from large clinical series have been affected.

Respiratory Tract
Recurrent upper respiratory tract infections such as otitis media and sinusitis are very common. Although the typical pathogens (S. pneumoniae, H. influenzae, Moraxella catarrhalis) are most common, unusual pathogens such as P. aeruginosa, yeast, and anaerobes may be present in chronic infections and result in complications such as invasive sinusitis and mastoiditis.

LIP is the most common chronic lower respiratory tract abnormality reported to the Centers for Disease Control and Prevention (CDC); historically this occurred in approximately 25% of HIV-infected children, although the incidence has declined in the cART era. LIP is a chronic process with nodular lymphoid hyperplasia in the bronchial and bronchiolar epithelium, often leading to progressive alveolar capillary block over months to years. It has a characteristic chronic diffuse reticuloendothelial pattern on chest radiography rarely accompanied by hilar lymphadenopathy, allowing a presumptive diagnosis to be made radiographically before the onset of symptoms. There is an insidious onset of tachypnea, cough, and mild to moderate hypoxemia with normal auscultatory findings or minimal rales. Progressive disease presents with symptomatic hypoxemia, which usually resolves with oral corticosteroid therapy, accompanied by digital clubbing. Several studies suggest that LIP is a lymphoproliferative response to a primary Epstein-Barr virus infection in the setting of HIV infection.

Most symptomatic HIV-infected children experience at least 1 episode of pneumonia during the course of their disease. S. pneumoniae is the most common bacterial pathogen, but P. aeruginosa and other Gram-negative bacterial pneumonias may occur in end-stage disease and are often associated with acute respiratory failure and death. Rarely, severe recurrent bacterial pneumonia results in bronchiectasis. Pneumocystis pneumonia is the most common opportunistic infection, but other pathogens, including CMV, Aspergillus, Histoplasma, and Cryptococcus, can cause pulmonary disease. Infection with common respiratory viruses, including respiratory syncytial virus, parainfluenza, influenza, and adenovirus, may occur simultaneously and have a protracted course and period of viral shedding from the respiratory tract. Pulmonary and extrapulmonary tuberculosis (TB) has been reported with increasing frequency in HIV-infected children in low-resource countries, although it is considerably more common in HIV-infected adults. Because of drug interactions between rifampin and ritonavir-based antiretroviral therapy and poor tolerability of the combination of multiple drugs required, treatment of TB/HIV coinfection is particularly challenging in children.

Cardiovascular System
Cardiac dysfunction, including left ventricular hypertrophy, left ventricular dilation, reduced left ventricular fractional shortening, and/or heart failure occurred in 18-39% of HIV-infected children in the pre-cART era; among those affected, lower nadir CD4 percent and a higher viral load were associated with lower cardiac function. However, a more recent evaluation of HIV-infected children taking long-term cART found that echocardiographic findings were closer to normal and none had symptomatic heart disease, suggesting that cART has a cardioprotective effect. What is still unclear is whether a higher rate of premature cardiovascular disease that has been seen in adults will be seen in children who have disease- or treatment-related hyperlipidemia, and prospective studies will be needed to assess this risk.

Gastrointestinal and Hepatobiliary Tract
Oral manifestations of HIV disease include erythematous or pseudo-membranous candidiasis, periodontitis (e.g., ulcerative gingivitis or periodontitis), salivary gland disease (i.e., swelling, xerostomia), and rarely ulcerations or oral hairy leukoplakia. Gastrointestinal tract involvement is common in HIV-infected children. A variety of pathogens can cause gastrointestinal disease, including bacteria (Salmonella, Campylobacter, MAC), protozoa (Giardia, Cryptosporidium, Isospora, microsporidia), viruses (CMV, HSV, rotavirus), and fungi (Candida). MAC and the protozoal infections are most severe and protracted in patients with severe CD4 cell depletion. Infections may be localized or disseminated and affect any part of the gastrointestinal tract from the oropharynx to the rectum. Oral or esophageal ulcerations, either viral in origin or idiopathic, are painful and often interfere with eating. AIDS enteropathy, a syndrome of malabsorption with partial villous atrophy not associated with a specific pathogen, has been postulated to be a result of direct HIV infection of the gut. Disaccharide intolerance is common in HIV-infected children with chronic diarrhea.

The most common symptoms of gastrointestinal disease are chronic or recurrent diarrhea with malabsorption, abdominal pain, dysphagia, and failure to thrive. Prompt recognition of weight loss or poor growth velocity in the absence of diarrhea is critical. Linear growth impairment often correlates with the level of HIV viremia. Supplemental enteral feedings should be instituted, either by mouth or with nighttime nasogastric tube feedings in cases associated with more severe chronic
growth problems; placement of a gastrostomy tube for nutritional sup-
plementation may be necessary in severe cases. The wasting syndrome,
defined as a loss of >10% of body weight, is not as common as failure to
thrive in pediatric patients, but the resulting malnutrition is associated
with a grave prognosis. Chronic liver inflammation evidenced by fluctu-
ating serum levels of transaminases with or without cholestasis is
relatively common, often without identification of an etiologic agent.
Cryptosporidial cholecystitis is associated with abdominal pain, jaun-
dice, and elevated γ-glutamyltransferase. In some patients, chronic
hepatitis caused by CMV, hepatitis B, hepatitis C, or MAC may lead to
portal hypertension and liver failure. Several of the antiretroviral drugs
or other drugs such as didanosine, protease inhibitors, nevirapine, and
dapson may also cause reversible elevation of transaminases.

Pancreatitis with increased pancreatic enzymes with or without
abdominal pain, vomiting, and fever may be the result of drug therapy
(e.g., with pentamidine, didanosine, or lamivudine) or, rarely, oppor-
tunistic infections such as MAC or CMV.

Renal Disease
Nephropathy is an unusual presenting symptom of HIV infection,
more commonly occurring in older symptomatic children. A direct
effect of HIV on renal epithelial cells has been suggested as the cause,
but immune complexes, hyperviscosity of the blood (secondary to
hyperglobulinemia), and nephrotoxic drugs are other possible factors.
A wide range of histologic abnormalities has been reported, includ-
ing focal glomerulosclerosis, mesangial hyperplasia, segmental necrotiz-
ing glomerulonephritis, and minimal change disease. Focal glomeruloscle-
rosis generally progresses to renal failure within 6–12 mo, but other
histologic abnormalities in children may remain stable without signifi-
cant renal insufficiency for prolonged periods. Nephritogenic sydrome is
the most common manifestation of pediatric renal disease, with edema,
pyaohbuninemia, proteinuria, and azotemia with normal blood pres-
sure. Cases resistant to steroid therapy may benefit from cyclosporine
therapy. Polyuria, oliguria, and hematuria have also been observed in
some patients.

Skin Manifestations
Many cutaneous manifestations seen in HIV-infected children are
inflammatory or infectious disorders that are not unique to HIV infec-
tion. These disorders tend to be more disseminated and respond less
consistently to conventional therapy than in the uninfected child. Seb-
orheic dermatitis or eczema that is severe and unresponsive to treat-
ment may be an early nonspecific sign of HIV infection. Recurrent or
chronic episodes of HSV, herpes zoster, molluscum contagiosum, flat
warts, anogenital warts, and candidal infections are common and may
be difficult to control.

Allergic drug eruptions are also common, in particular related to
nonnucleoside reverse transcription inhibitors, and generally respond
to withdrawal of the drug but also may resolve spontaneously without
drug interruption: rarely, progression to Stevens-Johnson syndrome
has been reported. Epidermal hyperkeratosis with dry, scaling skin is
frequently observed, and sparse hair or hair loss may be seen in the
later stages of the disease.

Hematologic and Malignant Diseases
Anemia occurs in 20–70% of HIV-infected children, more commonly
in children with AIDS. The anemia may be a result of chronic infection,
poor nutrition, autoimmune factors, virus-associated conditions
(hemophagocytic syndrome, parvovirus B19 red cell aplasia), or the
adverse effect of drugs (zidovudine).

Leukopenia occurs in almost 30% of untreated HIV-infected chil-
dren, and neutropenia often occurs. Multiple drugs used for treatment
or prophylaxis for opportunistic infections, such as Pneumocystis
pneumonia, MAC, and CMV, or antiretroviral drugs (zidovudine) may
also cause leukopenia and/or neutropenia. In cases in which therapy
cannot be changed, treatment with subcutaneous granulocyte colony-
stimulating factor may be necessary.

Thrombocytopenia has been reported in 10–20% of patients. The
etiology may be immunologic (i.e., circulating immune complexes or
antiplatelet antibodies) or, less commonly, from drug toxicity, or the
cause may be unknown. Antiretroviral (ARV) therapy may also reverse
thrombocytopenia in ARV-naïve patients. In the event of sustained
severe thrombocytopenia (<10,000 platelets/μL), treatment with intra-
venous immunoglobulin or anti-D offers temporary improvement in
most patients already taking ARVs. If ineffective, a course of steroids
may be an alternative, but consultation with a hematologist should be
sought. Deficiency of clotting factors (factors II, VII, IX) is not rare in
children with advanced HIV disease and is often easy to correct with
vitamin K. A novel disease of the thymus has been observed in a few
HIV-infected children. These patients were found to have characteris-
tic anterior mediastinal multilocular thymic cysts without clinical
symptoms. Histologic examination shows focal cystic changes, follicu-
lar hyperplasia, and diffuse plasmaocytosis and multinucleated giant
cells. Treatment with cART may result in resolution, or spontaneous
involution occurs in some cases.

In contrast to the more frequent occurrence in adults, malignant
diseases have been reported infrequently in HIV-infected children,
representing only 2% of AIDS-defining illnesses. Non-Hodgkin lym-
phoma, primary CNS lymphoma, and leiomysarcoma are the most
commonly reported neoplasms among HIV-infected children. Epstein-
Barr virus is associated with most lymphomas and with all leimyosar-
comas (see Chapter 254). Kaposi sarcoma, which is caused by human
herpesvirus 8, occurs frequently among HIV-infected adults but is
exceedingly uncommon among HIV-infected children in resource-rich
countries (see Chapter 257).

DIAGNOSIS
All infants born to HIV-infected mothers test antibody-positive at
birth because of passive transfer of maternal HIV antibody across the
placenta during gestation. Most uninfected infants without ongoing
exposure (i.e., who are not breastfed) lose maternal antibody between
6 and 12 mo of age and are known as seroreverters. Because a small
proportion of uninfected infants continue to test HIV antibody-
positive for up to 18 mo of age, positive IgG antibody tests, including
these rapid tests, cannot be used to make a definitive diagnosis of HIV
infection in infants younger than this age. The presence of IgA or IgM
anti-HIV in the infant's circulation can indicate HIV infection, because
these immunoglobulin classes do not cross the placenta; however, IgA
and IgM anti-HIV assays have been both insensitive and nonspecific
and therefore are not valuable for clinical use. In any child older than
18 mo of age, demonstration of IgG antibody to HIV by a repeatedly
reactive enzyme immunoassay and confirmatory Western blot test
establishes the diagnosis of HIV infection. Breastfed infants should
have antibody testing performed 12 wk following cessation of breast-
feeding to identify those who became infected at the end of lactation
by the HIV-infected mother. Certain diseases (e.g., syphilis, autoim-
mune diseases) may cause false-positive or indeterminate results. In
such cases specific viral diagnostic tests (see later) have to be done.

Several rapid HIV tests are currently available with sensitivity and
specificity better than those of the standard enzyme immunoassay.
Many of these tests require only a single step that allows test results to
be reported within less than 30 min. Incorporating rapid HIV testing
during delivery or immediately after birth is crucial for the care of
HIV-exposed newborns whose HIV status was unknown during preg-
nancy. A positive rapid test has to be confirmed by Western blot testing.
However, if 2 different rapid tests (testing different HIV-associated
antibodies) are positive, there is no need for further verification with
Western blot testing. In infants who are at risk of exposure to HIV-2
infection (e.g., born to an HIV-infected woman from West Africa), a
rapid test that can detect both HIV-1 and HIV-2 should be used.
However, if the HIV testing is negative or the Western blot test reveals
an unusual pattern, further diagnostic tests should be considered. In
addition, they should be tested with HIV-2 specific DNA PCR assay.

Viral diagnostic assays, such as HIV DNA or RNA PCR or HIV
culture, are considerably more useful in young infants, allowing a
definitive diagnosis in most infected infants by 1–6 mo of age
(Table 276–3). By 3–4 mo of age, the HIV culture and/or PCR identifies
all infected infants. HIV DNA PCR is the preferred virologic assay in
can be measured both in blood and urine, spines in the acute phase of the disease, declines during the asymptomatic phase, and rises again as the disease progresses.

**TREATMENT**

The currently available therapy does not eradicate the virus and cure the patient; instead it suppresses the virus for extended periods of time and changes the course of the disease to a chronic process. Decisions about ARV therapy for pediatric HIV-infected patients are based on the magnitude of viral replication (viral load), CD4 lymphocyte count or percentage, and clinical condition. Because ARV therapy changes as new drugs become available, decisions regarding therapy should be made in consultation with an expert in pediatric HIV infection. Plasma viral load monitoring and measurement of CD4 values have made it possible to implement rational treatment strategies for viral suppression as well as to assess the efficacy of a particular drug combination. The following principles form the basis for ARV treatment: (1) uninterrupted HIV replication causes destruction of the immune system and progression to AIDS; (2) the magnitude of the viral load predicts the rate of disease progression, and the CD4 cell count reflects the risk of opportunistic infections and HIV infection complications; (3) cART, which includes at least 3 drugs with at least 2 different mechanisms of action, should be the initial treatment. Potent combination therapy that suppresses HIV replication to an undetectable level restricts the selection of ARV-resistant mutants; drug-resistant strains are the major factor limiting successful viral suppression and delay of disease progression; (4) the goal of sustainable suppression of HIV replication is best achieved by the simultaneous initiation of combinations of ARV agents to which the patient has not been exposed previously and that are not crossresistant to drugs with which the patient has been treated previously; (5) drug-related interactions and toxicities should be minimal; and (6) adherence to the complex drug regimens is crucial for a successful outcome.

**Combination Therapy**

As of 2014, 21 ARV drugs were approved by the FDA for use in HIV-infected adults and adolescents and 19 of them (Table 276-4) for the pediatric population (most of them available as liquid, powder, or small tablet/capsules). ARV drugs are categorized by their mechanism of action, such as preventing viral entrance into CD4+ T cells, inhibiting the HIV reverse transcriptase or protease enzymes, or inhibiting integration of the virus into the human DNA. Within the reverse transcriptase inhibitors, a further subdivision can be made: *nucleoside* (or *nucleotide*) reverse transcriptase inhibitors (NRTIs) and *nonnucleoside reverse transcriptase inhibitors* (NNRTIs) (see Fig. 276-3). The NRTIs have a similar structure to the building blocks of DNA (e.g., thymidine, cytosine). When incorporated into DNA, they act like chain terminators and block further incorporation of nucleosides, preventing viral DNA synthesis. Among the NRTIs, thymidine analogs (e.g., stavudine, zidovudine [ZDV]) are found in higher concentrations in activated or dividing cells producing >99% of the HIV virions population) and nonthymidine analogs (e.g., didanosine, lamivudine) have more activity in resting cells, which account for <1% of the HIV virions but may serve as a reservoir for HIV. Suppression of replication in both populations is thought to be an important component of long-term viral control. NNRTIs (i.e., nevirapine, efavirenz, etravirine, rilpivirine) act differently than the NRTIs. They attach to the reverse transcriptase and restrict its motility, reducing the activity of the enzyme. The *protease inhibitors* are potent agents that act farther along the viral replicative cycle. They bind to the site where the viral long poly-peptides are cut to individual, mature, and functional core proteins that produce the infectious virions before they leave the cell. The virus entry into the cell is a complex process that involves several cellular receptors and fusion. Several drugs have been developed to prevent this process. The *fusion inhibitor*, enfuvirtide, which binds to viral gp41, causes conformational changes that prevent fusion of the virus with the CD4+ cell and entry into the cell. Maraviroc is an example of a selective CCR5 coreceptor antagonist that blocks the attachment of the virus to this chemokine (an essential process in the viral binding and fusion to the

PCR, polymerase chain reaction.

developed countries. Almost 40% of infected newborns have positive test results in the 1st 2 days of life, with >90% testing positive by 2 wk of age. Plasma HIV RNA assays, which detect viral replication, are as sensitive as the DNA PCR for early diagnosis. HIV culture has similar sensitivity to HIV DNA PCR but is more technically complex and expensive, and results are often not available for several weeks compared with 2-3 days for PCR. The commercially available HIV-1 assays are not designed for quantification of HIV-2 RNA and thus should not be used to monitor patients with this infection.

Viral diagnostic testing should be performed within the 1st 12-24 hr of life. Almost 40% of HIV-infected children can be identified at this time. It seems that many of these children have a more rapid progression of their disease and deserve more aggressive therapy. Data suggest that if anti-HIV treatment will start at this point, the outcome will be much better. In exposed children with negative virologic testing at 1-2 days of life, additional testing should be done at 1-2 mo of age and at 4-6 mo of age; some also favor testing at age 14 days as almost 90% of the infected infants can be identified and ARV therapy can be initiated earlier. A positive virologic assay (i.e., detection of HIV by PCR, culture, or p24 antigen) suggests HIV infection and should be confirmed by a repeat test on a second specimen as soon as possible. A diagnosis of HIV infection can be made with 2 positive virologic test results obtained from different blood samples.

The perinatal use of ARV prophylaxis (either single drug or combination) to prevent vertical transmission has not affected the predictive value of viral diagnostic testing. In addition, the intensive antiviral combinations (protease inhibitors) in pregnant women do not affect the DNA PCR; however, these combinations may have an effect on the RNA PCR. HIV infection can be reasonably excluded if an infant has had at least 2 negative virologic test results with at least 1 test performed at ≥4 mo of age. In some parts of the world where non–subtype B strains are common (i.e., outside of the United States), interpretation of a negative PCR test result should be done with caution because the assay may not detect the particular subtype (e.g., group O). Close clinical monitoring with serologic testing (by 18 mo of age) or culture (if possible) is recommended. In older infants, 2 or more negative HIV antibody tests performed at least 1 mo apart past 6 mo of age in the absence of hypogammaglobulinemia or clinical evidence of HIV disease can reasonably exclude HIV infection. The infection can be excluded definitively if the same parameters are met when the infant is at least 18 mo of age.

Few surrogate markers (e.g., neopterin, β2-microglobin) were shown to improve the predictive information of CD4+ T-cell counts. These markers may be useful in places where CD4+ T-cell counts are not available. Neopterin is an early marker of HIV infection and its level rises further as the disease progress to AIDS. β2-Microglobin, which...

<td>&lt;6 yr: consult with expert 6-18 yr: 15 to &lt;20 kg: 150 mg + 100 RTV qd 20 to 40 kg: 200 mg + 100 RTV qd &gt;40 kg, adolescent and adult: 300 mg + 100 RTV qd or 400 mg if unboosted with food  If given with EFV (600 mg) or TDF (300 mg): 400 mg + 100 RTV qd</td>
<td>Common: elevation of indirect bilirubin; headache, arthralgia, depression, insomnia, nausea, vomiting, diarrhea, paresthesias  Less common: prolongation of PR interval on electrocardiogram (ECG); rash, rarely Stevens-Johnson syndrome, diabetes mellitus, nephrolithiasis</td>
<td>Administer with food to increase absorption. Review drug interactions before initiating because ATV inhibits CYP3A4, CYP1A2, CYP2C9, and UGT1A1 enzymes. Use with caution with cardiac conduction disease or liver impairment. Combination with EFV should not be used in treatment-experienced patients because it decreases ATV levels. TDF, antacids, H₂-receptor antagonists, and proton-pump inhibitors decreases ATV concentrations. Patients taking buffered ddd should take it at least 2 hr before ATV</td>
</tr>
<tr>
<td>Darunavir  Prezista, DRV  Tablets: 75, 150, 400, 600, 800 mg  Suspension: 100 mg/mL</td>
<td>&lt;3 yr: consult with expert 3 to &lt;18 yr: 10 to &lt;15 kg: 20 mg/kg DRV + 3 mg/kg RTV 15 to &lt;30 kg: 375 mg DRV + 50 mg RTV bid 30 to &lt;40 kg: 450 DRV mg + 100 mg RTV bid &gt;40 kg, adolescent and adult: 600 mg DRV + 100 mg RTV bid or Adolescent (&gt;12 yr and 40 kg) and adult: 800 mg DRV + 100 mg RTV qd with food  If any DRV resistance is found: 600 mg DRV = 100 mg RTV bid</td>
<td>Common: diarrhea, nausea, vomiting, abdominal pain, fatigue, headache  Less common: skin rashes (including Stevens-Johnson syndrome), lipid and liver enzyme elevations, hyperglycemia, fat maldistribution</td>
<td>DRV should not be given without food. Contraindicated for concurrent therapy with cisapride, ergot alkaloids, benzodiazepines, pimozide, or any major CYP3A4 substrates. Use with caution in patients taking strong CYP3A4 inhibitors, or moderate/strong CYP3A4 inducers. Adjust dose with concurrent rifamycin therapy. Contains sulfa moiety; potential for cross-sensitivity with sulfonamide class</td>
</tr>

<tr>
<td><strong>Fosamprenavir</strong>&lt;br&gt;Lexiva, FPV&lt;br&gt;Tablets: 700 mg&lt;br&gt;Suspension: 50 mg/mL</td>
<td>6 mo to 18 yr:&lt;br&gt;- &lt;11 kg: 45 mg/kg FPV + 7 mg/kg RTV bid&lt;br&gt;- 11 to &lt;15 kg: 30 mg/kg + 3 mg/kg RTV bid&lt;br&gt;- 15 to &lt;20 kg: 23 mg/kg + 3 mg/kg RTV bid&lt;br&gt;- &gt;20 kg: 18 mg/kg (max: 700 mg) + 3 mg/kg (max: 100 mg) RTV bid&lt;br&gt;Adolescent &gt;18 yr and adult:&lt;br&gt;- FPV 700 mg + RTV 100 mg bid&lt;br&gt;- FPV 1,400 mg + RTV 200 mg qd</td>
<td>Common: nausea, vomiting, perioral paresthesias, headache, rash, lipid abnormalities&lt;br&gt;Less common: Stevens-Johnson syndrome, fat redistribution, neutropenia, elevated creatine kinase, hyperglycemia, diabetes mellitus, elevated liver enzymes, angioedema, nephrolithiasis</td>
<td>Should be given with food. FPV is an inhibitor of the CYP450 system and an inducer, inhibitor, and substrate of CYP3A4, which can cause multiple drug interactions. Use with caution in sulfa-allergic individuals</td>
</tr>
<tr>
<td><strong>Indinavir</strong>&lt;br&gt;Crixivan, IDV&lt;br&gt;Capsule: 100, 200, 400 mg</td>
<td>Infants: not approved&lt;br&gt;Children: 500 mg/m² every 8 hr (max dose: 800 mg per dose) or 400 mg/m² + RTV 100 mg/m² bid&lt;br&gt;Adolescent and adult: 800 mg IDV + 100 or 200 mg RTV bid</td>
<td>Common: nausea, abdominal pain, hyperbilirubinemia, headache, dizziness, lipid abnormalities, nephrolithiasis, metallic taste&lt;br&gt;Less common: fat redistribution, hyperglycemia, diabetes mellitus, hepatitis, acute hemolytic anemia</td>
<td>Administer on empty stomach if given without RTV. Reduce dose (600 mg IDV every 8 hr) with mild to moderate liver dysfunction. Adequate hydration (at least 48 oz fluid/day in adults) necessary to minimize risk of nephrolithiasis. IDV is cytochrome P450 3A4 inhibitor and substrate, which can cause multiple drug interactions: rifampin reduces levels; ketoconazole, ritonavir, and other protease inhibitors increase IDV levels. Do not coadminister with EFV, aztreonam, carbapenems, azithromycin.</td>
</tr>
<tr>
<td><strong>Lopinavir/Ritonavir</strong>&lt;br&gt;Kaletra, LPV/r&lt;br&gt;Tablets: 100/25 mg, 200/50 mg&lt;br&gt;Solution: 80/20 mg per/mL (contains 42% alcohol)</td>
<td>14 days to 18 yr: 300 mg/m² LPV +75 mg/m² RTV bid&lt;br&gt;Adolescent (&gt;18 yr) and adult:&lt;br&gt;- 400 mg LPV +100 mg RTV bid or 800 mg LPV +200 mg RTV qd&lt;br&gt;IF taken with NVP, EFV, FPV, or NFV:&lt;br&gt;- LPV 600 mg + RTV 150 mg bid</td>
<td>Common: diarrhea, headache, nausea and vomiting, lipid elevation&lt;br&gt;Less common: fat redistribution, hyperglycemia, diabetes mellitus, pancreatitis, hepatitis, PR interval prolongation</td>
<td>No food restrictions. High-fat meal and flavoring of solution to increase palatability are recommended if oral solution is used. Interacts with drugs using CYP3A4, which can cause multiple drug interactions</td>
</tr>
<tr>
<td><strong>Nelfinavir</strong>&lt;br&gt;Viracept, NFV&lt;br&gt;Tablet: 250, 625 mg</td>
<td>&lt;2 yr: not recommended&lt;br&gt;Children 2-13 yr: 45-55 mg/kg bid&lt;br&gt;Adolescents and adults: 1,250 mg bid</td>
<td>Common: diarrhea asthenia, abdominal pain, skin rashes, lipid abnormalities&lt;br&gt;Less common: exacerbation of liver disease, fat redistribution, hyperglycemia, diabetes mellitus, elevation of liver enzymes</td>
<td>Administer with a meal to optimize absorption; avoid acidic food or drink (e.g., orange juice). Tablet can be crushed or dissolved in water to administer as a solution. Drug interactions: Nelfinavir inhibits CYP3A4 activity, which may cause multiple drug interactions. Rifampin, phenobarbital, and carbamazepine reduce levels. Ketoconazole, ritonavir, nelfinavir, and other protease inhibitors increase levels. Do not coadminister aztreonam, carbapenems, azithromycin. RTV boosting has no effect.</td>
</tr>

Continued
CD4+ cells). **Integrase inhibitors** like raltegravir block the enzyme that catalyzes the incorporation of the viral genome into the host’s DNA.

While the principal site of viral replication is lymphoid tissue, sanctuary sites such as the CNS may harbor residual virions with the potential to be a source of local or persistent disease. Impaired penetration of drugs to these compartments could result in development of resistance. Impaired penetration of toxicities (see Table 276-4), and complex drug–drug interactions may be feasible. Combinations of 3 drugs, a thymidine analog NRTI (abacavir or ZDV) and a nonthymidine analog NRTI (lamivudine) to suppress replication in both active and resting cells and a protease inhibitor (atazanavir or lopinavir/ritonavir) or an NNRTI (efavirenz) produce prolonged viral suppression. Less-potent combinations, such as triple NRTIs (abacavir, zidovudine, lamivudine), may be considered in special situations (e.g., children <3 yr with concomitant tuberculosis when nevirapine-based ART is unacceptable or in rare cases when there are concerns about significant drug interactions or adherence to a complex drug regimen). The use of 3 drugs from 3 different classes should be avoided as it has the potential to cause resistance to 3 drug classes. Combination treatment increases the rate of toxicities (see Table 276-4), and complex drug–drug interactions exist among many of the antiretroviral drugs. Many protease inhibitor drugs are inducers or inhibitors of the cytochrome P450 system and are therefore likely to have serious interactions with multiple drug classes, including nonsedating antihistamines and psychotropic, vasoconstrictor, antimycobacterial, cardiovascular, analgesic, and gastrointestinal drugs (cisapride). Whenever new medications are added

</table>

Antiretroviral drugs often have significant drug–drug interactions, with each other and with other classes of medicines, which should be reviewed before initiating any new medication.

The information in this table is not all-inclusive. Updated and additional information on dosing, drug–drug interactions, and toxicities is available on the AIDSinfo website at [http://www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov)

Modified from the Guidelines for use of antiretroviral agents in pediatric HIV infection. [http://aidsinfo.nih.gov/contentFiles/PediatricGuidelines.pdf](http://aidsinfo.nih.gov/contentFiles/PediatricGuidelines.pdf)
to an antiretroviral treatment regimen, especially a protease inhibitor–containing regimen, a pharmacist and/or HIV specialist should be consulted to address possible drug interactions. The inhibitory effect of ritonavir (a protease inhibitor) on the cytochrome P450 system has been exploited, and small doses of the drug are added to several other protease inhibitors (e.g., lopinavir, tipranavir, atazanavir, darunavir) to slow their metabolism by the P450 system and to improve their pharmacokinetic profile. This strategy provides more effective drug levels with less toxicity and less-frequent dosing. Recently, the development of cobicistat provides an alternative to ritonavir. Although cobicistat is a potent inhibitor of cytochrome P450 3A, it is a weak inhibitor of CYP2D6 and other CYP isozymes (e.g., CYP1A2), making pharmacologic interactions with many drugs more predictable than with ritonavir, which is also active against these isozymes. Preliminary studies with cobicistat suggest that it has a good tolerability profile and less effect on adipocytes (resulting in milder accumulation of lipid and response to insulin). The better solubility of cobicistat compared to ritonavir may foster the availability of more single-tablet combination regimens with cobicistat.

**Adherence**

Adherence to the medication schedules and dosages is fundamental to ARV therapy success. Therefore, assessment of the likelihood of adherence to treatment is an important factor in deciding whether and when to initiate therapy. Numerous studies show that compliance of <90% results in less-successful suppression of the viral load. In addition, several studies document that almost half of the pediatric patients surveyed were nonadherent to their regimen. Poor adherence to prescribed medication regimens results in subtherapeutic drug concentrations and exacerbates development of resistance. Several barriers to adherence are unique to children with HIV infection. Combination antiretroviral regimens are often unpalatable and require extreme dedication on the part of the caregiver and child; a reluctance to disclose the child’s disease to others reduces social support; there may be a tendency to skip doses if the caregiver is not around or when the child is in school. Adolescents have other issues that reduce adherence. Denial and/or fear of their infection, unstructured lifestyle, conduct or emotional disorder, wishing to be the same as their peers, depression, fatigue from taking a lifelong regimen, anxiety, and alcohol and substance abuse are just a few of the barriers for a long-term adherence in this growing population. These and other barriers make participation of the family in the decision to initiate therapy essential. Intensive education on the relationship of drug adherence to viral suppression, training on drug administration, frequent follow-up visits, peer support, pager messaging, and commitment of the caregiver and the patient (despite the inconvenience of adverse effects, dosing schedule) are critical for successful antiviral treatment. Multiple methods such as viral load response, self-reporting of missed doses during the last 3-7 days, and pharmacy/pill counting or monitoring drugs’ concentrations in the blood should be used to assess adherence.

**Initiation of Therapy**

The decision on when to initiate cART is controversial and keeps evolving. Even the recent adult guidelines that recommend initiation of cART in individuals with CD4 cell counts <500 cells/μL acknowledges that treatment of individuals with higher CD4 cell counts may be beneficial. Therefore, the following recommendations for pediatric patients are only accurate for the time they were written (August 2014), and physicians providing care to few HIV-exposed or infected children should periodically consult physicians with expertise in pediatric HIV infection as well as the U.S. pediatric guidelines for treatment of HIV-infected children found at [http://aidsinfo.nih.gov](http://aidsinfo.nih.gov).

Children younger than 1 yr of age are at high risk for disease progression, and immunologic and virologic tests to identify those likely to develop rapidly progressive disease are less predictive than in older children. Therefore, HIV-infected infants younger than 1 yr of age should be treated with ARV agents as soon as the diagnosis of HIV infection has been confirmed, regardless of clinical or immunologic status or viral load. Data suggest that HIV-infected infants who are treated before the age of 3 mo control their HIV infection better than infants whose ARV therapy started later than 3 mo of age. Some of these infants even become HIV seronegative and lose their HIV specific immune response.

There is still a debate on when to start therapy in children older than 1 yr of age. The 2014 U.S. Pediatric Guidelines Panel recommends, with varying strength of the recommendations, treating all children ≥1 year of age with Stage 3 CD4 counts, significant clinical symptoms, or HIV RNA >100,000 copies/mL. Children 1–6 years of age should be treated with CD4 counts between 500–999 cells/mm³, and treatment should be considered if the child has minimal/no symptoms and a CD4 count ≥2000 cells/mm³. Children 26 years of age should be treated with CD4 counts between 200–499 cells/mm³, and treatment should be considered if the child has minimal/no symptoms and a CD4 count ≥500 cells/mm³. These guidelines are reviewed yearly, and care providers should check for revisions at [http://aidsinfo.nih.gov](http://aidsinfo.nih.gov). Some clinicians advocate treating all HIV-infected children regardless of their clinical stage, viral load, or CD4 T-cell status to prevent the inevitable immunologic deterioration that will otherwise occur.

**Dosing**

Children are usually treated with higher doses (per kg weight) than adults because of reduced absorption or increased elimination. Data on ARV drug dosages for neonates, especially premature infants, are often limited. Because of the immaturity of the neonatal liver, there must often be an increase in the dosing interval of drugs primarily cleared through hepatic glucuronidation. In addition, drug absorption from the gastrointestinal tract may be problematic. Therefore, monitoring of drugs’ plasma levels should be considered, if available.

Adolescents should have ARV dosages prescribed on the basis of Tanner staging of puberty rather than on the basis of age. Pediatric dosing ranges should be used during early puberty (Tanner stages I, II, and III), whereas adult dosing schedules should be followed in adolescents in late puberty (Tanner stages IV and V). Efavirenz should be avoided in females who may become pregnant and do not use effective contraception because of its potential teratogenicity. Because some protease inhibitors may change the metabolism of oral contraceptives and decrease their effectiveness, monthly injections of medroxyprogesterone (DMPA) or use of an intrauterine device should be considered, or the protease inhibitor can be changed, if needed, to an integrase inhibitor, which has no interaction with estrogen-based contraceptives.

**Changing Antiretroviral Therapy**

Therapy should be changed when the current regimen is judged ineffective as evidenced by increase in viral load, deterioration of the CD4 cell count, or clinical progression. Development of toxicity or intolerance to drugs is another reason to consider a change in therapy. When a change is considered, the patient and family should be reassessed for adherence problems. Because adherence is a major issue in this population, resistance testing (while on ARV medications) is important in identifying adherence issues (e.g., detectable virus sensitive to current drugs will suggest lack of adherence) or development of resistance (e.g., evidence of resistance mutations to given drugs). In both situations, other contributing factors such as poor absorption, incorrect dose, or drug–drug interactions should be carefully reviewed. While considering possible new drug choices, potential cross-resistance should be addressed. In addition, few patients who have virologic failure may still demonstrate improved CD4 cell counts (discordant response). Impaired replication ability of the resistant virus (also called reduced viral fitness) and enhanced CTL effects are some of the reasons for this discordant response. In these patients, delay in changing therapy should be considered as long as the immunologic benefit is evident. Ideally, when a decision is made to change the ARV therapy, all drugs should be changed. However, in many situations (previous ARV experience, intolerance, toxicity) this is not possible, thus at least 2 drugs should be changed based on the resistance mutation genotype or phenotype (if available) or evaluation of the drugs used in the previous regimen.
Monitoring Antiretroviral Therapy

To ensure proper monitoring, the CD4 cells count, viral load, complete blood count, chemistries, urinalysis, and serum lipids should be done before initiation or change in cART to have a baseline for comparisons while on treatment. Children need to be seen within 1-2 wk after initiation of new ARV therapy to ensure compliance and to screen for potential side effects. Virologic and immunologic surveillance (using HIV RNA copy number and CD4 lymphocyte count or percentage) as well as clinical assessment should be performed regularly during ARV therapy. Initial virologic response (i.e., at least a 50% [0.7 log10] reduction in viral load) should be achieved within 4-8 wk of initiating antiretroviral therapy. The maximum response to therapy usually occurs within 12-16 wk, but may be later (24 wk) in very young infants. Thus, HIV RNA levels should be measured at 4 wk and 3-4 mo after therapy initiation. Once an optimal response has occurred, viral load should then be measured at least every 3-6 mo. If the response is unsatisfactory, another viral load should be performed as soon as possible to verify the results before a change in therapy is considered. The CD4 cells respond more slowly to successful treatment and, therefore, can be monitored less frequently. Potential toxicity should be monitored closely for the 1st 8-12 wk (including complete blood count, serum chemistries, urinalysis, and lipids), and if no clinical or laboratory toxicity is documented, a follow-up visit every 3-4 mo is adequate. Monitoring for potential toxicity should be tailored to the drugs taken. These toxicities include but are not limited to hematologic complications (e.g., ZDV); hypersensitivity rash (e.g., efavirenz); lipoatrophy (e.g., redistribution of body fat seen with NRTIs, protease inhibitors); hyperlipidemia (elevation of cholesterol and triglyceride concentrations); hyperglycemia, and insulin resistance (e.g., protease inhibitors); mitochondrial toxicity leading to severe lactic acidosis (e.g., stavudine, didanosine); electrocardiogram abnormalities (e.g., atazanavir, lopinavir); abnormal bone mineral metabolism (e.g., tenofovir); and hepatic toxicity, including severe hepatomegaly with steatosis.

Resistance to Antiretroviral Therapy

Young children usually are at greater risk than adults for developing resistance because they have higher viral loads than adults and are more limited by which ARV options are available. The high mutation rate of HIV (mainly as a result of the absence of error-correcting mechanisms) severely impairs the success of ARV therapy. Failure to reduce the viral load to <400 copies/mL increases the risk for developing resistance. Even effectively treated patients do not completely suppress viral replication, and persistence of HIV transcription and evolution of envelope sequences continues in the latent cellular reservoirs. The accumulation of resistance mutations progressively diminishes the potency of the ARV therapy and challenges the physician to find new regimens. For some drugs (e.g., nevirapine, lamivudine) a single mutation is associated with resistance, whereas for other drugs (e.g., ZDV, lopinavir) several mutations are needed before resistance develops. Testing for drug resistance, especially when devising a new regimen, is becoming the standard of care. Two types of tests are available: (1) The phenotypic assay measures the virus susceptibility in various concentrations of the drug that allows calculation of the drug concentration that inhibits viral replication by 50% (IC50). The ratio of the IC50 and a reference virus IC50 is reported as fold resistance change. (2) The genotypic assay predicts the virus susceptibility from mutations identified in the HIV genome isolated from the patient. Several online sites (e.g., http://hivdb.stanford.edu) can assist in interpreting the test’s results. Several studies show that treatment success is higher in patients whose ARV therapy was guided by genotype or phenotype testing. Neither method may detect drug resistance if the amount of the resistant virus is <10% of the circulating population or if it is present only in the latent reservoir.

It is recommended to test for drug resistance before initiating therapy and before changing treatment because of failure. When changing therapy, the resistance test results should be considered in the context of previous resistance tests results, if done, and drugs used in previous regimens.

Supportive Care

Even before ARV drugs were available, a significant impact on the quality of life and survival of HIV-infected children was achieved when supportive care was given. A multidisciplinary team approach is desirable for successful management. Following initiation or change of cART, more frequent visits or contacts with the patient/caregivers for support and education will help in their acceptance and adjustment to the new regimen and will contribute to a better adherence. Close attention should be paid to nutritional status, which is often delicately balanced and may require aggressive supplementation. Painful oropharyngeal lesions and dental caries may interfere with eating, and thus routine dental evaluations and careful attention to oral hygiene should be encouraged. Paradoxically, an increasing number of adolescents with perinatally acquired or behavioral risk-acquired disease are obese. Some teens experience ARV-related central lip-accumulation, but others have poor dietary habits and inactivity as the cause of their obesity, in parallel to epidemic obesity in the United States. Development should be evaluated regularly with provision of necessary physical, occupational, and/or speech therapy. Recognition of pain in the young child may be difficult, and effective nonpharmacologic and pharmacologic protocols for pain management should be instituted.

All infants born to HIV-infected mothers should receive ZDV prophylaxis for 4-6 wk. Additional ARV therapy should be considered if the risk of acquiring HIV by the newborn is high. For example, if the mother has not received cART during pregnancy, 3 doses of nevirapine (at birth, 48 hr, and 144 hr of life) should be added. If the mother’s HIV status is unknown, rapid HIV-testing of either the mother or the newborn should be done immediately after delivery and if positive, ARV prophylaxis should be started as soon as possible without waiting for the confirmatory test results. Guidelines for prophylaxis in newborns are updated at least yearly and can be accessed at http://www.aidsinfo.nih.gov. A complete blood count, differential leukocyte count, and platelet count should be performed at 4 wk of age to monitor ZDV toxicity. These tests should be continued every 1-3 mo to assess the hematologic effect of ZDV and prophylactic trimethoprim-sulfamethoxazole (TMP-SMZ), if given. If the child is found to be HIV infected, baseline laboratory assessment (e.g., CD4 count, HIV RNA, complete blood count, chemistries) should be done and cART should be started as soon as possible. Viral load and CD4 lymphocyte counts should be performed at 1 and 3 mo of age and should be repeated every 3 mo. All HIV-exposed and infected children should receive standard pediatric immunizations. In general, live oral polio vaccine should not be given (Fig. 276-4). The risk and benefits of rotavirus vaccination should be considered in infants born to HIV-infected mothers. Because <1% of these infants in resource-rich countries will develop HIV infection, the vaccine should be given. In other situations, the considerable attenuation of the vaccine’s strains should be taken into account and unless the infant has clinical symptoms of AIDS or CD4 <15%, vaccination seems to be appropriate. Other live bacterial vaccines (e.g., bacillus Calmette-Guérin) should be avoided because of the high incidence of bacillus Calmette-Guérin–related disease in HIV-infected infants. Varicella and measles-mumps-rubella vaccines are recommended for children who are not severely immunosuppressed (i.e., CD4 cell percentage ≥15%), but these vaccines should not be given to severely immunocompromised children (i.e., CD4 cell <15%). Of note, prior immunizations do not always provide protection, as evidenced by outbreaks of measles and pertussis in immunized HIV-infected children. Durability of vaccine-induced titers is often short, especially if vaccines are administered when the child’s CD4 cell is <15%, and re-immunization when the CD4 count has increased (i.e., >15%) may be indicated.

Prophylactic regimens are integral for the care of HIV-infected children. All infants between 4-6 wk and 1 yr of age who are known to be HIV-infected should receive prophylaxis to prevent P. carinii (also called P. jiroveci) infection regardless of the CD4 cell count or percentage (Tables 276-5 and 276-6). Infants exposed to HIV-infected mothers should receive the same prophylaxis until they are proven to be noninfected; however, prophylaxis does not have to be initiated if there is strong presumptive evidence of noninfection (i.e., non-breastfed
The National Perinatal HIV Hotline (1-888-448-8765) provides consultation on all aspects of perinatal HIV care.

*Footnotes*:

*See text.

† Contraindicated in children with AIDS or CD4<sup>+</sup> < 15%. Give 2 doses 1-3 mo apart.

‡ Revaccination is recommended every year. Attenuated vaccine can be used >2 yr of age only if CD4<sup>+</sup> > 15%.

§ Revaccination with pneumococcal polysaccharide vaccine (PPV) every 5 yr.

¶ Two doses at least 6 mo apart.

* First dose 6 through 14 wk of age and final dose no later than 8 mo 0 days of age. If using Rotarix, only 2 doses (2 and 4 mo) are needed.

The National Perinatal HIV Hotline (1-888-448-8765) provides consultation on all aspects of perinatal HIV care.

*More frequent monitoring (e.g., monthly) is recommended for children whose CD4 counts or percentages are approaching the threshold at which prophylaxis is recommended.

Prophylaxis should be considered on a case-by-case basis for children who might otherwise be at risk for PCP, such as children with rapidly declining CD4 counts or percentages or children with category C conditions. Children who have had PCP should receive PCP prophylaxis until their CD4 count is >20% (for >6 yr of age) or >25% (for 2-5 yr of age) on continuous cART.

In the setting of primary prophylaxis against opportunistic infections, the child should be tested more frequently. Of note, the sensitivity of purified protein derivation is reduced in severely immunocompromised patients and other laboratory tests should be used. For severe adverse reactions to TMP-SMZ, alternative therapies include dapsone, atovaquone, and aerosolized pentamidine.

Prophylaxis against MAC should be offered to HIV-infected children with advanced immunosuppression (i.e., CD4 lymphocyte count <750 cells/µL in children younger than 1 yr of age, <500 cells/µL in children 1-2 yr of age, <75 cells/µL in children 2-5 yr of age, and <50 cells/µL in children >6 yr of age) (see Table 276-6). The drugs of choice are azithromycin (20 mg/kg [maximum: 1,200 mg] once a week PO or 5 mg/kg [maximum: 250 mg] once daily PO) or clarithromycin (7.5 mg/kg bid PO). In rare situations, rifabutin 300 mg qd can be an alternative for children older than 6 yr of age.

Based on adult data, primary prophylaxis against opportunistic infections may be discontinued if patients have experienced sustained (>6 mo duration) immune reconstitution with cART, even if they had previous opportunistic infections such as *Pneumocystis* pneumonia or disseminated MAC. HIV-infected children are at higher risk for TB and thus should have tuberculin skin testing (5 tuberculin units purified protein derivation) for TB at least once per year; an induration of 5 mm or more should be considered positive. If the child is living in close contact with a person with TB, the child should be tested more frequently. Of note, the sensitivity of purified protein derivation is reduced in severely immunocompromised patients and other laboratory tests should be used. For example, assays that determine IFN-γ release from lymphocytes following stimulation by specific *Mycobacterium tuberculosis* antigens were found to be more specific than the skin testing in adults. Limited data suggest that they are less sensitive in diagnosing TB in children, and therefore caution should be used in interpreting negative results of such tests in children. The "Guidelines for Prevention and Treatment of

*Fig. 276-3*)
Opportunistic Infections Among HIV-Exposed and HIV-Infected Children* (http://aidsinfo.nih.gov) should be consulted for these and other opportunistic infections that may occur in these populations. To reduce the incidence of opportunistic infections, parents should be counseled about (1) the importance of good hand washing, (2) avoiding raw or undercooked food (Salmonella), (3) avoiding drinking or swimming in lake or river water or being in contact with young farm animals (Cryptosporidium), and (4) the risk of playing with pets (Toxoplasma and Bartonella from cats, Salmonella from reptiles).

PROGNOSIS

The improved understanding of the pathogenesis of HIV infection in children and the availability of more effective antiretroviral drugs has changed the prognosis considerably. The earlier cART is started, the better the prognosis; a clinical trial aims to start treatment as close to delivery as possible will test the possibility of curing perinatally infected newborns. In settings with ready access to early diagnosis and antiretroviral therapy, progression of the disease to AIDS has significantly diminished. Since the advent of cART in the mid-1990s, mortality in perinatally infected children has declined more than 90% and many of the children survive to adolescence and adulthood. Even with only partial reduction of viral load, children may have both significant immunologic and clinical benefits. In general, the best prognostic indicators are the sustained suppression of plasma viral load and restoration of a normal CD4+ lymphocyte count. If determinations of viral load and CD4 lymphocytes are available, the results can be used to evaluate prognosis. It is unusual to see rapid progression in an infant with a viral load <100,000 copies/mL. In contrast, a high viral load (>100,000 copies/mL) over time is associated with greater risk for disease progression and death. CD4 lymphocyte percentage is another prognostic indicator, and the mortality rate is higher in patients with a CD4 lymphocyte percentage <15%. To define prognosis more accurately, the use of changes in both markers (CD4 lymphocyte percentage and plasma viral load) is recommended.

Even in resource-limited countries where ARV therapy and molecular diagnostic tests are less available, the use of cART had a substantial benefit on the survival of HIV-infected children and reduced the hazard of mortality by 75%. Children with opportunistic infections (e.g., Pneumocystis pneumonia, MAC), encephalopathy and regressing developmental milestones, or wasting syndrome have the worst prognosis, with 75% dying before 3 yr of age. A higher risk of mortality was documented in children who did not receive TMP-SMZ preventive therapy. Persistent fever and/or oral thrush, serious bacterial infections (meningitis, pneumonia, sepsis), hepatitis, persistent anemia (<8 g/dL), and/or thrombocytopenia (<100,000/µL) also suggest a poor outcome, with >30% of such children dying before 3 yr of age. In contrast, lymphadenopathy, splenomegaly, hepatomegaly, lymphoid interstitial pneumonitis, and parotitis are indicators of a better prognosis.

PREVENTION

Use of antiretroviral therapy for interruption of perinatal transmission from mother-to-child has been one of the greatest achievements of HIV research. Maternal cART is documented to decrease the rate of

*Information in these guidelines might not represent FDA approval or FDA-approved labeling for products or indications. Specifically, the terms “safe” and “effective” might not be synonymous with the FDA-defined legal standards for product approval.

†Daily trimethoprim-sulfamethoxazole (TMP-SMZ) reduces the frequency of certain bacterial infections. Compared with weekly dapsone, daily dapsone is associated with lower incidence of PCP but higher hematologic toxicity and mortality. Patients receiving therapy for toxoplasmosis with sulfadiazine-pyrimethamine are protected against PCP and do not need TMP-SMZ. TMP-SMZ, dapsone-pyrimethamine, and possibly atovaquone (with or without pyrimethamine) protect against toxoplasmosis; however, data have not been prospectively collected.

‡Substantial drug interactions can occur between rifamycins (i.e., rifampin and rifabutin) and protease inhibitors and nonnucleoside reverse transcriptase inhibitors. A specialist should be consulted.

§Children routinely being administered intravenous immunoglobulin (IVIG) should receive VarizIG if the last dose of IVIG was administered more than 21 days before exposure.

¶Protection against toxoplasmosis is provided by the preferred anti-Pneumocystis regimens and possibly by atovaquone.

perinatal HIV-1 transmission to <2%, and <1% if the mother’s viral RNA level is <1,000 copies/mL at delivery. Therefore, it is recommended that all pregnant women be tested for HIV and if positive, treated with a cART regimen, irrespective of viral load or CD4 count during pregnancy. This should be in conjunction with 4-6 wk of ZDV prophylaxis for the infant and with collaboration between the HIV-specialist and the obstetrician. Cesarean section (C-section) as a prevention strategy was examined in a multinational meta-analysis, which showed that the combination of elective C-section and maternal ZDV treatment reduced transmission by 87%. However, these data were obtained prior to the advent of cART, and the additional benefit of elective C-section to the cART-treated mother whose viral load is <1,000 copies/mL is negligible. Thus, elective C-section at 38 wk of gestation should be considered only for women whose viral load is >1,000 copies/mL in late gestation, to further reduce the risk of vertical transmission.

A multinational randomized, controlled trial in non-breastfed neonates whose mothers received no ARVs during pregnancy showed that prophylaxis with a two- or three-drug ARV regimen is superior to ZDV alone for the prevention of intrapartum HIV transmission. Based on these data, the U.S. Guidelines Panel recommends that infants born to HIV-infected women who have received no antepartum or only intrapartum ARVs, or who have HIV RNA >1000 copies/mL near delivery, should receive prophylaxis with ZDV for 6 wk combined with three doses of NVP in the 1st wk of life (i.e., at birth, 48 hr later, and 96 hr after the second dose), begun as soon after birth as possible (see Table 276-4).

The WHO recommends that all pregnant women receive a cART regimen appropriate for their own health, which should be continued at least throughout breastfeeding (in resource-limited areas) and for the remainder of their lives. This approach has the potential to reduce transmission during breastfeeding and future pregnancies, lowers the transmission risk to sexual partners, improves maternal survival, and promotes simplified universal treatment regimens. Breastfed infants should receive NVP for 6 wk if the mother is receiving cART, or NVP for the duration of breastfeeding if the mother is not on therapy. Formula-fed infants in resource-limited countries should receive ZDV bid or NVP qd for 6 wk.

Although the most effective way to prevent postpartum transmission of HIV is to eliminate breastfeeding altogether and substitute replacement feeding, there is evidence that early weaning may not be safe in resource-limited settings because of the high risk of malnutrition and diarrhea in formula-fed infants without a consistent source of clean water. Furthermore, exclusive breastfeeding (no additional solids or fluids other than water) results in less transmission than mixed feeding. Guidelines have evolved to recommend that HIV-infected mothers living in resource-limited settings should breastfeed their infants until at least 12 mo of age, with exclusive breastfeeding for the 1st 6 mo, and ARVs should continue to be provided, either to the mother or to the infant, at least until 1 wk after all breastfeeding has ceased. In settings where there are safe alternatives to breastfeeding, formula feeding is recommended. U.S. guidelines for prevention of mother-to-child transmission are regularly updated at http://aidsinfo.nih.gov/ and the international guidelines are regularly updated at the WHO website (http://www.who.int/hiv/topics/mtct/en/).

Now that it is clear that perinatal transmission can be reduced dramatically by treating pregnant mothers, a compelling argument can be made for prenatal identification of HIV-1 infection in the mother. The benefit of therapy both for the mother’s health and to prevent transmission to the infant cannot be overemphasized. The recommended universal prenatal HIV-1 counseling and HIV-1 testing for all pregnant women has reduced the number of new infections dramatically in many areas of the United States and Europe. For women not tested during pregnancy, the use of rapid HIV antibody testing during labor or on the 1st day of the infant’s life is a way to provide perinatal prophylaxis to an additional group of at-risk infants.

Prevention of sexual transmission involves avoiding the exchange of bodily fluids. In sexually active adolescents, condoms should be an integral part of programs to reduce sexually transmitted diseases, including HIV-1. Unprotected sex with older partners or with multiple partners and use of recreational drugs is common among HIV-1–infected adolescents, increasing their risk. Educational efforts about avoidance of risk factors are essential for older school-age children and adolescents and should begin before the onset of sexual activity. In addition, promising research for sexually active adults may translate to increased prevention for adolescents. Three African trials demonstrated that male circumcision was associated with a 50-60% reduction in risk of HIV acquisition in young men. For women, use of a 1% vaginal gel formulation of tenofovir during intercourse was found to reduce HIV acquisition by nearly 40%. Other topical microbicides are being investigated. A double-blind study of preexposure prophylaxis in MSM using once daily dosing of coformulated tenofovir and emtricitabine resulted in a 44% reduction in the incidence of HIV (95% confidence interval, 15-63; P = 0.005). Of interest, the incidence of HIV transmission was reduced by 73% when participants took the drug on 90% or more days. In addition, a large randomized multinational clinical trial of HIV serodiscordant adults demonstrated that effective ARV therapy in the HIV-infected partner reduced secondary transmission to an uninfected sexual partner by 96%. However, none of the studies that have shown promise for prevention in at-risk populations has included adequate representation in youth, making it difficult to interpret the effect on this population.

Despite prolonged suppression of viremia, it is obvious that cART may not fully restore health and may be associated with long-term toxicity. In addition, adherence is a major challenge and constrained resources will limit the ability to expand cART to all patients who need it. However, recent discoveries of new antiretroviral drugs, new vaccines, and advances in our understanding of HIV latency are encouraging developments on the long road to a cure.

Bibliography is available at Expert Consult.
ETIOLOGY
Human T-lymphotropic viruses 1 (HTLV-1) and 2 (HTLV-2) are members of the Deltaretrovirus genus of the Retroviridae family, which are single-stranded RNA viruses that encode reverse transcriptase, an RNA-dependent DNA polymerase that transcribes the single-stranded viral RNA into a double-stranded DNA copy. HTLV-1 was the first human retrovirus to be associated with cancer, as the cause of adult T-cell leukemia/lymphoma (ATL).

HTLV-1 and -2 share a genome homology of approximately 65% and infect T cells, B cells, and synovial cells via the ubiquitous glucose transporter type 1, which serves as the virus receptor. The genome contains \( \text{gag}, \text{pol}, \) and \( \text{env} \) genes and the \( \text{pX} \) region, which encodes nonstructural proteins. The nonstructural proteins include the Tax and Rex regulatory proteins, the novel proteins essential for virus spread (p30, p12, and p13), and the antisense-encoded HTLV-1 basic leucine zipper factor. Circular viral DNA is transported into the nucleus where it is integrated into chromosomal DNA (provirus), evading the typical mechanisms of immune surveillance and facilitating lifelong infection. The host response is mediated by cytotoxic T lymphocytes, resulting in lysis of infected cells. An exuberant inflammatory response with overproduction of cytokines contributes to developing nonmalignant disease.

EPIDEMIOLOGY
HTLV-1 infects 15-20 million persons globally. It is endemic in south-western Japan (where >10% of adults are seropositive), areas of the
Caribbean, including Jamaica and Trinidad (up to 6%), and in parts of sub-Saharan Africa (up to 5%). Lower seroprevalence rates are found in South America (up to 2%) and Taiwan (0.1-1%). There is microclustering with marked variability within geographic regions.

The seroprevalence of HTLV-1 and HTLV-2 in the United States in the general population is 0.01-0.03% for each virus, with higher rates with increasing age. The prevalence of HTLV-1 infection is highest in babies born in endemic areas or in persons who have had sexual contact with persons from endemic areas. The prevalence of HTLV-2 infection correlates with intravenous illicit drug use. A prevalence of approximately 18% was found in a study of illicit drug users in the United States, often with concomitant HIV infection.

HIV-1 and -2 are transmitted as cell-associated viruses by vertical transmission from mother to child and horizontal transmission through genital secretions, contaminated blood products, and intravenous illicit drug use. Higher maternal HIV-1 proviral load may be associated with greater risk of vertical transmission, which occurs primarily via breastfeeding from infected mothers with a 3-fold increased risk of transmission with breastfeeding for longer than 6 mo. Intrauterine and intrapartum transmissions account for <5% of vertical transmissions. In Japan, approximately 20-25% of children born to infected mothers become infected, and more than 90% of HTLV-1-infected children have HTLV-1–infected mothers. HTLV-2 may also be transmitted via breastfeeding, but it has a slightly lower reported transmission rate via breast milk of approximately 14%.

**DIAGNOSIS**

HTLV-1 and HTLV-2 infections are diagnosed by screening using 2nd-generation enzyme immunoassay with confirmation by immunoblot, indirect immunofluorescence, or line immunoassays. Polymerase chain reaction can also be used to distinguish HTLV-1 from HTLV-2 infection.

**CLINICAL MANIFESTATIONS**

The lifetime risk of disease associated with HTLV-1 infection is estimated at 5-10% and is highest following vertical transmission. HTLV-1 is associated with ATL and several nonmalignant conditions, including the neurodegenerative disorder HTLV-1–associated myelopathy (HAM), also known as tropical spastic paraparesis and sometimes termed HAM/ tropical spastic paraparesis. The geographic epidemiologic characteristics of ATL and HAM are similar. HTLV-1–associated arthropathy mimics rheumatoid arthritis, including a positive rheumatoid factor. Treatment is with antiinflammatory agents. HTLV-1–associated uveitis may be unilateral or bilateral, is more common among women, and resolves spontaneously, although it often recurs within 1-3 yr. Topical corticosteroids hasten recovery. HTLV-1–associated infective dermatitis is a chronic and recurrent eczematous disease occurring during childhood and adolescence. HTLV-1 infection predisposes to disseminated and recurrent Strongyloides stercoralis infection, increased risk of developing tuberculosis disease following latent infection, and severe scabies.

**Human T-Cell Lymphotropic Virus-2**

HTLV-2 was originally identified in patients with hairy cell leukemia, although most patients with hairy cell leukemia are seronegative for HTLV-2 infection. HTLV-2 has been rarely isolated from patients with leukemias or with myelopathies resembling HAM, and there is limited evidence of disease specifically associated with HTLV-2 infection.

**PREVENTION**

Routine antibody testing of all blood products using HTLV-1 viral lysate began in the United States in 1988 and missed 30-58% of HTLV-2 infections. Combination HTLV-1/2 antibody testing was implemented in 1997. Formula feeding in lieu of breastfeeding of infants of HTLV-1–infected mothers is an effective means of controlling endemic HTLV-1 transmission. No vaccine is available.

**Bibliography is available at Expert Consult.**
Human T-Lymphotropic Viruses (1 and 2)

**Bibliography**

The transmissible spongiform encephalopathies (TSEs) are slow infections of the human nervous system, consisting of at least 4 diseases of humans (Table 278-1): kuru; Creutzfeldt-Jakob disease (CJD) with its variants—sporadic CJD (sCJD), familial CJD (fCJD), iatrogenic CJD (iCJD), and new-variant or variant CJD (vCJD); Gerstmann-Sträussler-Scheinker syndrome (GSS); and fatal familial insomnia (FFI), or the even more rare sporadic fatal insomnia syndrome. TSEs also affect
animals; the most common and best-known TSEs of animals are scrapie in sheep, bovine spongiform encephalopathy (BSE or mad cow disease) in cattle, and a chronic wasting disease (CWD) of deer, elk, and moose found in parts of the United States and Canada. All TSEs have similar clinical manifestations and histopathology, and all are "slow" infections with very long asymptomatic incubation periods (often years), durations of several months or more, and overt disease affecting only the nervous system. TSEs are relentlessly progressive after illness begins and invariably fatal. The most striking neuropathologic change that occurs in each TSE, to a greater or lesser extent, is spongiform degeneration of the cerebral cortical gray matter.

ETIOLOGY
The TSEs are transmissible to susceptible animals by inoculation of tissues from affected subjects. Although the infectious agents replicate in some cell cultures, they do not achieve the high titers of infectivity found in brain tissues or cause recognizable cytopathic effects in cultures. Most studies of TSE agents have used in vivo assays, relying on the transmission of typical neurologic disease to animals as evidence that the agent was present and intact. Inoculation of susceptible recipient animals with small amounts of infectious TSE agent results, months later, in the accumulation in tissues of large amounts of agent with the same physical and biologic properties as the original agent. The TSE agents display a spectrum of extreme resistance to inactivation by a variety of chemical and physical treatments that is unknown among conventional pathogens. This characteristic, as well as their partial sensitivity to protein-disrupting treatments and their consistent association with abnormal isoforms of a normal host-encoded protein (prion protein or PrP), stimulated the hypothesis that the TSE agents are probably subviral in size, composed of protein, and devoid of nucleic acid.

The term prion (for proteinaceous infectious agent) is now widely used for such agents. The prion hypothesis proposes that the molecular mechanism by which the pathogen-specific information of TSE agents is propagated involves an end- or self-replicating change in the folding host-encoded PrP associated with a transition from an \( \alpha \)-helix-rich structure in the native protease-sensitive conformation (cellular PrP or...
PrP) to a  β-sheet–rich structure in the protease-resistant conformation associated with infectivity. The existence of a second host-encoded protein—termed “protein X”—that participates in the transformation was also postulated to explain certain otherwise puzzling findings but never identified.

The prion hypothesis is still not universally accepted; it relies on the postulated existence of a genome-like coding mechanism based on differences in protein folding that have not been satisfactorily explained at a molecular level. In addition, it has yet to account convincingly for the many biologic strains of TSE agent that have been observed, although strain-specific differences in the abnormal forms of the PrP have been found and proposed as providing a plausible molecular basis for the coding. It fails to explain why pure PrP uncontaminated with nucleic acid from an infected host has not transmitted a convincingly typical spongiform encephalopathy associated with a serially self-propagating agent. Also troubling, in several experimental models and human illnesses, abnormal PrP and infectivity were not consistently associated. Particularly problematic is the finding that some illnesses associated with mutations in the PRNP gene and accompanied by abnormal PrP failed to transmit infection to animals. If the TSE agents ultimately prove to consist of protein and only protein, without any obligatory nucleic acid component, then the term prion will indeed be appropriate and the early proponents of the prion hypothesis will prove to have been prescient. If the agents are ultimately found to contain small nucleic acid genomes, then they might better be considered atypical viruses, for which the term virino has been suggested. Until the actual molecular structure of the infectious TSE pathogens and the presence or absence of a nucleic acid genome are rigorously established, it seems less contentious to continue calling them TSE agents, although many authorities now use the term prion (sometimes referring to the agent of a TSE and sometimes to the abnormal protein, even when nontransmissible).

The earliest evidence that abnormal proteins are associated with the TSE was morphologic: scrapie-associated fibrils were found in extracts of tissues from patients and animals with spongiform encephalopathies but not in normal tissues. Scrapie-associated fibrils resemble but are distinguishable from the amyloid fibrils that accumulate in the brains of patients with Alzheimer disease. A group of antigenically related protease-resistant proteins (PrPs) proved to be components of scrapie-associated fibril and to be present in the amyloid plaques found in the brains of patients and animals with TSEs. The abnormal forms of PrP are variously designated PrPSEN (scrapie-type PrP), PrP-res (protease-resistant PrP), PrPSEN (TSE-associated PrP), or PrPSEN (disease-associated PrP) by different authorities.

It remains unclear whether abnormal PrP constitutes the complete infectious particle of spongiform encephalopathies, is a component of other particles, or is a pathologic host protein not usually separated from the actual infectious entity by currently used techniques. The demonstration that PrP is encoded by a normal host gene seemed to favor the last possibility. Several studies suggest that agent-specific pathogenic information can be transmitted and replicated by different conformations of a protein with the same primary amino acid sequence in the absence of agent-specific nucleic acids. Properties of 2 fungal proteins were found to be heritable without encoding in nucleic acid, although those properties have not been transmitted to recipient fungi as infectious elements. Whatever its relationship to the actual infectious TSE particles, PrP clearly plays a central role in susceptibility to infection, because the normal PrP must be expressed in mice and cattle if they are to acquire a TSE or to sustain replication of the infectious agents. Furthermore, inherited normal variations in PrP phenotype are associated with increased susceptibility to vCJD and (to a lesser extent) to sCJD and with occurrence of iCJD.

PrPs are glycoproteins; protease-resistant PrPs, when aggregated, have the physical properties of amyloid proteins. The PrPs of different species of animals are very similar in their amino acid sequences and antigenicity but are not identical in structure. The primary structure of PrP is encoded by the host and is not altered by the source of the infectious agent provoking its formation. The function of the ubiquitous protease-sensitive PrP precursor (designated PrPSEN or PrP-sen, for protease-sensitive PrP) in normal cells is unknown; it binds copper and may play some role in normal synaptic transmission, but it is not required for life or for relatively normal cerebral function in mice and cattle. As noted, expression of PrP is required both for development of scrapie disease and for replication of the transmissible scrapie agent in animals. The degree of homology between amino acid sequences of PrPs in different animal species may correlate with the "species barrier" that affects susceptibility of animals of 1 species to infection with a TSE agent adapted to grow in another species.

Attempts to find particles resembling those of viruses or virus-like agents in brain tissues of humans or animals with spongiform encephalopathies have been unsuccessful. Peculiar tubulovesicular structures reminiscent of some viruses have been seen in thin sections of TSE-infected brain tissues and cultured cells but not in normal cells. It has never been convincingly established that those structures are associated with infectivity.

**EPIDEMIOLOGY**

Kuru once affected many children of both sexes ≥ 4 yr of age, adolescents, and young adults (mainly women) living in 1 limited area of Papua New Guinea. The complete disappearance of kuru among people born after 1957 suggests that the practice of ritual cannibalism (thought to have ended that year) was probably the only mechanism by which the infection was spread in Papua New Guinea.

CJD, the most common human spongiform encephalopathy, was formerly thought to occur only in older adults; however, iCJD and, much more rarely, sCJD (to date, 7 reports in adolescents—1 a 14 yr old girl) have affected young people. A single case of sporadic fatal insomnia was recognized in a U.S. adolescent. GSS has not been diagnosed in children or adolescents. vCJD, however, has a peculiar predilection for younger people. Of 174 cases of vCJD reported through 2010 in the United Kingdom, all except 23 were in people younger than 40 yr of age and 22 were younger than 20 yr of age; the youngest age at onset was 12 yr. sCJD has been recognized worldwide, at yearly rates of 0.25-2 cases/million population (not age-adjusted), with CJD feci of considerably higher incidence among Libyan Jews in Israel, in isolated villages of Slovakia, and in other limited areas. Sporadic CJD has not been convincingly linked to any common exposure, and the source of infection remains unknown. Proponents of the prion hypothesis are convinced that PrP can spontaneously misfold, becoming self-replicating and causing sCJD; skeptics favor infection with some ubiquitous TSE agent which, fortunately, has a very low attack rate except in persons with certain mutations in the PRNP gene. Neither of those possible etiologies has been proven. Person-to-person spread has been confirmed only for iatrogenic cases. Spouses and household contacts of patients are at very low risk of acquiring CJD, although 2 instances of conjugal CJD have been reported. However, medical personnel exposed to brains of patients with CJD may be at some increased risk; at least 20 healthcare workers have been recognized with the disease.

The striking resemblance of CJD to scrapie prompted a concern that infected sheep tissues might be a source of spongiform encephalopathy in humans. No reliable epidemiologic evidence suggests that exposure to potentially scrapie-contaminated animals, meat, meat products, or experimental preparations of the scrapie agent have transmitted a TSE to humans. The potential of the CWD agent to infect human beings has also not been demonstrated but remains under investigation; deer, elk, and moose in 15 U.S. states and 2 Canadian provinces have been naturally infected; monkeys have been experimentally infected by injections with deer tissues containing the CWD agent. Exposure to contaminated meat, including venison from animals infected with the CWD agent, has not been implicated as a risk factor for sCJD.

The outbreak of BSE among cattle (possibly infected by eating scrapie-agent–contaminated meat-and-bone meal added to feed) was first recognized in the United Kingdom in 1986 and later reported in native cattle of 24 other countries, including Canada and the United States. The finding of a new TSE in ungulate and feline animals in British zoos and later in domestic cats raised a fear that some TSE agent (probably a strain of the scrapie agent), having crossed the species barrier from sheep to cattle, had acquired a broadened range
of susceptible hosts, posing a potential danger for humans. That remains a plausible explanation for the occurrence of vCJD, first described in adolescents in Britain in 1996 and as of November 2013 affecting at least 177 people in the United Kingdom (not counting a disturbing number of people with evidence of possible asymptomatic or “preclinical” vCJD infection) and more than 50 in other countries: 27 in France, 5 in Spain, 4 in Ireland, 3 in the Netherlands, 2 each in Italy and Portugal, and single cases in Japan and Saudi Arabia. Variant CJD has also occurred in former U.K. residents living in Ireland (2 cases), France (1 case), Canada (1 case), Taiwan (1 case), and the United States (2 cases); 2 additional cases of vCJD—one in the United States and 1 in Canada—have been reported in former long-time residents of Saudi Arabia, a country that has not recognized BSE but might have imported contaminated meat products from the United Kingdom. A third case of vCJD was previously confirmed in a Saudi citizen residing in Saudi Arabia. Examination of resected appendixes in the United Kingdom for evidence of subclinical infection with prions suggested that many more people than expected had subclinical infection than those recognized with actual vCJD.

Iatrogenic transmissions of CJD have been recognized for more than 30 yr (Table 278–2). Such accidental transmissions of CJD have been attributed to use of contaminated neurosurgical instruments (no case reported since 1980) or operating facilities, use of cortical electrodes contaminated during epilepsy surgery, injections of human cadaveric pituitary growth hormone and gonadotropin (no longer marketed in the United States), and transplantation of contaminated corneas and allografts of human dura mater used as a surgical patching material. Pharmaceuticals and tissue grafts derived from or contaminated with human neural tissues, particularly when obtained from unselected donors and large pools of donors, pose special risks. Studies of animals experimentally infected with TSE agents first suggested that blood and blood components from humans with preclinical CJD infections might pose a risk of transmitting disease to recipients, and since the 1980s such blood components have been withdrawn as a precaution in the United States when a donor was later found to have CJD and blood products were still in-date. While no epidemiologic study identified any subject exposed to such products obtained from donors later diagnosed with sporadic or vCJD, a surveillance program in the United Kingdom has already reported vCJD in 3 recipients of nonleukoreduced red blood cells from donors later diagnosed with vCJD; there was autopsy evidence of a preclinical vCJD infection in a fourth red cell recipient who died of another disease. Evidence of a preclinical vCJD infection was also found at autopsy in a patient with hemophilia A who was treated with human plasma-derived coagulation factor VIII to which at least 1 vCJD-infected donor contributed; the coagulation factor involved was never licensed in the United States.

*There have been 28 cases reported among approximately 8,000 recipients of human cadaveric growth hormone in the United States; the remaining cases have been reported in other countries.

†The second transfusion-transmitted case of vCJD (Peden AH, Head MW, Ritchie DL, et al: Preclinical vCJD after blood transfusion in a PRNP codon 129 heterozygous patient, Lancet 364:527–529, 2004) died of unrelated causes about 5 yr after transfusion but was found to have accumulations of abnormal PrP in spleen and cervical lymph node—a finding unique to vCJD and interpreted as probable preclinical infection.

‡The diagnosis of vCJD infection attributed to treatment with human plasma-derived coagulation factor VIII (UK Health Protection Agency vCJD abnormal prion protein found in a patient with haemophilia at post mortem, Press release 17 February 2009: http://www.hpa.org.uk/webw/HPAweb&HPAwebStandard/HPAweb_C/1234859690542?pa=1231252394302) was also supported by immunohistochemical testing for abnormal PrP in the spleen of a person who died of other causes. Both patients with “preclinical” infections are thought to have died during the asymptomatic incubation period of vCJD.

### PATHOGENESIS AND PATHOLOGY

The probable portal of entry for the TSE agent in kuru is thought to have been either through the gastrointestinal tract or lesions in the mouth or integument incidentally exposed to the agent during cannibalism. Patients with vCJD (and animals with BSE and BSE-related TSEs) are thought to have been similarly infected with the BSE agent through exposure to a contaminated beef product, possibly through the intestinal tract. Except after direct introduction into the nervous system, the first site of replication of TSE agents appears to be in tissues of the reticuloendothelial system. TSE agents have been detected in low tiers in blood of experimentally infected animals (mice, monkeys, hamsters, and sheep) and in the blood of persons with vCJD and perhaps sCJD; infectivity was mainly associated with nucleated cells, although plasma contained a substantial portion of total infectivity in blood. Circulating lymphoid cells seem to be required to infect mice by peripheral routes. Limited evidence suggests that TSE agents also spread to the central nervous system by ascending peripheral nerves. Several researchers claim to have developed tests that detected the CJD agent in human blood, although most attempts have failed. To date no blood-based test has been validated for antemortem testing of either humans or animals.

In human kuru, it seems probable that the only portal of exit of the agent from the body, at least in quantities sufficient to infect others, was through infected tissues exposed during cannibalism. In iatrogenically transmitted CJD, the brains and eyes of patients with CJD have been the probable sources of contamination. Experimental transmission of the agent to animals from kidney, liver, lung, lymph node, and spleen showed that those tissues as well as cerebrospinal fluid (CSF) sometimes contain the CJD agent; none of those sources has been implicated in accidental transmission of CJD to humans. At no time during the course of any TSE have antibodies or cell-mediated immunity to the infectious agents been convincingly demonstrated in either patients or animals. However, mice must be immunologically competent to be infected with the scrapie agent by peripheral routes of inoculation.

Typical changes in TSE include vacuolation and loss of neurons with hypertrophy and proliferation of glial cells, most pronounced in the cerebral cortex in patients with CJD and in the cerebellum in those with kuru. The central nervous system lesions are usually most severe in or even confined to gray matter, at least early in the disease. Loss of myelin appears to be secondary to degeneration of neurons. There generally is no inflammation, but a marked increase in the number and size of astrocytes is usual. Spongiform changes are not a striking autopsy finding in patients with FFI, and neuronal degeneration and gliosis are largely restricted to thalamic nuclei.

Amyloid plaques are found in the brains of all patients with GSS and in at least 70% of those with kuru. These plaques are less common in patients with CJD. Amyloid plaques are most common in the cerebellum but occur elsewhere in the brain as well. In brains of patients with vCJD, plaques surrounded by halos of vacuoles (described as flower-like or florid plaques) have been a consistent finding. TSE amyloid plaques react with antiserum prepared against PrP. Even in the absence of plaques, extracellular PrP can be detected in the brain parenchyma by immunostaining.
**CLINICAL MANIFESTATIONS**

Kuru, no longer seen, is a progressive degenerative disease of the cerebellum and brainstem with less obvious involvement of the cerebral cortex. The first sign of kuru was usually cerebellar ataxia followed by progressive incoordination. Coarse, shivering tremors were characteristic. Variable abnormalities in cranial nerve function appeared, frequently with impairment in conjugate gaze and swallowing. Patients died of inanition and pneumonia or of burns from cooking fires, usually within 1 yr after onset. Although changes in mentation were common, there was no frank dementia or progression to coma, as in CJD. There were no signs of acute encephalitis such as fever, headaches, and convulsions.

CJD occurs throughout the world. Patients initially have either sensory disturbances (most often visual) or confusion and inappropriate behavior, progressing over weeks or months to frank dementia, akinetic mutism, and ultimately coma. Some patients have cerebellar ataxia early in disease, and most patients experience myoclonic jerking movements. Mean survival of patients with sCJD has been <1 yr from the earliest signs of illness, although approximately 10% live for 2 yr. Variant CJD (Table 278-3) differs from the more common sCJD: patients with vCJD are much younger at onset (as young as 12 yr) and more often present with complaints of dysesthesia and subtle behavioral changes, often mistaken for psychiatric illness. Severe mental deterioration occurs later in the course of vCJD. Patients with vCJD have survived substantially longer than those with sCJD. (Attempts have been made to subclassify cases of CJD based on electrophoretic differences in PrP[15] and variation in its sensitivity to digestion with the proteolytic enzyme proteinase (PK); the different variants are said to have somewhat different clinical features, including duration of illness, though all are ultimately fatal.)

GSS is a familial disease resembling CJD but with more prominent cerebellar ataxia and amyloid plaques. Dementia may appear only late in the course, and the average duration of illness is longer than typical sCJD. Progressively severe insomnia and dysautonomia as well as ataxia, myoclonus, and other signs resembling those of CJD and GSS characterize FFI and sporadic fatal insomnia. A case of sporadic fatal ataxia, myoclonus, and other signs resembling those of CJD and GSS occurred in a young adolescent. GSS has not been diagnosed in children or adolescents.

A novel "prion disease" has been reported that is expressed in several generations with an autosomal dominant pattern associated with a unique mutation in the PRNP gene. The affected persons were middle-aged with a history of chronic diarrhea for years plus autonomic neuropathy and modest mental impairment but without full-blown dementia; PK-resistant PrP deposits with amyloid properties occurred in the brain, lymphoid tissues, kidney, spleen, and intestinal tract. The disease was not successfully transmitted to 3 lines of mice susceptible to several TSEs. It is not clear that such a syndrome—not a spongiform encephalopathy—and apparently not associated with an infectious agent—should be lumped together with TSEs. It might well result from the abnormal PRNP gene product itself; if so, it would not pose the same potential threat to public health as do the TSEs.

**DIAGNOSIS**

Diagnosis of spongiform encephalopathies is most often determined on clinical grounds after excluding other diseases. The presence of 14-3-3 protein (see "Laboratory Findings") in CSF may aid in distinguishing between CJD and Alzheimer disease, although this is not a consideration in children. Elevations of 14-3-3 protein levels in CSF are not specific to TSEs and are common in viral encephalitis and other conditions causing rapid necrosis of brain tissue. Brain biopsy may be diagnostic of CJD, but it can be recommended only if a potentially treatable disease remains to be excluded or if there is some other compelling reason to make an antemortem diagnosis. Definitive diagnosis usually requires microscopic examination of brain tissue obtained at autopsy. The demonstration of protease-resistant PrP proteins in brain extracts can be useful to augment histopathologic diagnosis. Accumulation of the abnormal PrP in lymphoid tissues, even before the onset of neurologic signs, is typical of vCJD. Tonsil biopsy may avoid the need for brain biopsy when antemortem diagnosis of vCJD is indicated. Transmission of disease to susceptible animals by inoculation of brain suspension must be reserved for cases of special research interest.

**LABORATORY FINDINGS**

Virtually all patients with typical sporadic, iatrogenic, and familial forms of CJD have abnormal electroencephalograms (EEGs) as the disease progresses; the background becomes slow and irregular with diminished amplitude. A variety of paroxysmal discharges such as slow waves, sharp waves, and spike-and-wave complexes may also appear, and these may be unilateral or focal or bilaterally synchronous. Paroxysmal discharges may be precipitated by loud noise. Many patients have typical periodic suppression-burst complexes of high-voltage slow activity on EEG at some time during the illness. Patients with vCJD have had only generalized slowing, without periodic bursts of high-voltage discharges on EEG. CT or MRI may show cortical atrophy and large ventricles late in the course of CJD. Many patients with vCJD have an increase in density of the pulvinar on MRI. Reliable interpretation of the images might best be left to experienced radiologists.

‡Characterized by an excess of high molecular mass band (diglycosylated) and 19 kDa nonglycosylated band glycoform of PrP-res (Collinge J, Sidle KC, Meads J, et al: Molecular analysis of prion strain variation and the aetiology of "new variant" CJD, Nature 383:685-690, 1996).
§BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt-Jakob disease; EEG, electroencephalogram; Met, codon 129 of one PRNP gene encoding for methionine; PRNP, prion protein-encoding gene; PrP, prion protein.
There may be modest elevation of CSF protein content in patients with TSE. Unusual protein spots were observed in CSF specimens after 2-dimensional separation in gels and silver staining; the spots were identified as 14-3-3 proteins, normal proteins (not related to PrP) abundant in neurons but not ordinarily detected in CSF. However, the finding of 14-3-3 protein in CSF has also been detected in CSF specimens from some patients with acute viral encephalitides and recent cerebral infarctions, and thus is not specific to CJD. Finding the 14-3-3 protein in CSF is neither sensitive nor specific but has been of some help in confirming the diagnosis of vCJD, especially when accompanied by increases in other cellular proteins. Diagnosis usually rests on recognizing the typical constellation of clinical findings, clinical course, and testing (CSF examination, CT or MRI, EEG), confirmed by histopathology and detection of PrP\textsuperscript{Sc} in brain tissues at autopsy (or, less often, by tonsil or brain biopsy).

**TREATMENT**

No treatment has proven effective. Studies of cell cultures and rodents experimentally infected with TSE agents suggested that treatment with chlorpromazine, quinacrine, and tetracyclines might be of benefit, especially during the incubation period. Early reports of clinical trials based on those studies have been discouraging, and it seems unlikely that the severe brain damage found in late disease can be reversed by such treatment. Infusions with pentosan polysulfate directly into the cerebral ventricles appear to have delayed the progression of vCJD in at least 1 patient but did not reverse earlier brain damage. Appropriate supportive care should be provided to all CJD patients as for other progressive fatal neurologic diseases. On the basis of experimental studies in animals, several prophylactic postexposure treatment regimens have been suggested, but none has been widely accepted.

**GENETIC COUNSELING**

TSE sometimes occurs in families in a pattern consistent with an autosomal dominant mode of inheritance. In patients with a family history of CJD, the clinical and histopathologic findings are similar to those seen in sporadic cases. In the United States, only approximately 10% of cases of CJD are familial. GSS and FFI are always familial. In some affected families, approximately 50% of siblings and children of a patient with a familial TSE eventually acquire the disease; in other families, the “penetrance” of illness may be less.

The gene encoding for PrP is closely linked if not identical to that controlling the incubation periods of scrapie in sheep and both scrapie and CJD in mice. The gene encoding PrP in humans is designated the PRNP gene and is located on the short arm of chromosome 20. It has an open reading frame of about 759 nucleotides (253 codons), in which more than 20 different point mutations and a variety of inserted sequences encoding extra tandem-repeated octapeptides are linked to the occurrence of spongiform encephalopathy in families with a pattern consistent with autosomal dominance of variable penetrance.

The same nucleotide substitution at codon 178 of the PRNP gene associated with CJD in some families has been found in all patients with FFI. Homozygosity for valine and especially for methionine at codon 129 seems to increase susceptibility to iCJD and sCJD. Almost all patients with vCJD to be genotyped have been homozygous for methionine at codon 129 of the PRNP gene. A few probable preclinical vCJD infections and 1 clinically typical case of vCJD have been reported in persons with other genotypes. It is of interest that when the PRNP genes from appendices containing accumulations of what appears to be PrP\textsuperscript{Sc} in the United Kingdom were sequenced, a surprising number were homozygous for valine—the genotype of only approximately 10% of U.K. subjects and never found in a case of vCJD. The significance of this finding is not clear. U.K. authorities have adopted the precautionary assumption that some persons with PrP\textsuperscript{Sc} in lymphoid tissues may have latent infections. Whether the blood and tissues of such persons are infectious is unknown.

Although the interpretation of these findings in regard to the prion hypothesis is in dispute, persons from families with CJD or GSS who have the associated mutations in the PRNP gene have a high probability of eventually acquiring spongiform encephalopathy. The significance of mutations in the PRNP genes of individuals from families with no history of spongiform encephalopathy is not known. It seems wise to avoid alarming those from unaffected families who have miscellaneous mutations in the PRNP gene, because the implications are not yet clear; in the United States, such persons are deferred from donating blood if a blood relative has been diagnosed with a TSE.

**PROGNOSIS**

The prognosis of all spongiform encephalopathies is uniformly poor. Approximately 10% of patients may survive for longer than 1 yr, but the quality of life is poor.

**FAMILY SUPPORT**

The CJD Foundation (http://www.cjdfoundation.org), organized and maintained by family members and friends of patients with CJD and related disorders, working closely with the Centers for Disease Control and Prevention (http://www.cdc.gov/nccidod/dvrd/prions) and with the National Prion Disease Pathology Surveillance Center, Case Western Reserve University, Cleveland, Ohio (http://www.cjdsurveillance.com), is a support and educational group and a useful source of information regarding available resources for those dealing with the diseases.

**PREVENTION**

Exposure to the BSE agent in meat products clearly poses a special danger. Authorities in Canada, the United States, and other countries have responded by implementing progressively more stringent agricultural and public health measures during the past 20 yr; with elimination of most bovine-derived materials from animal feeds probably the most effective measure. Three cases of BSE in native cattle have been recognized in the United States since 2004—the last in 2012; a case was also recognized in a Canadian cow imported into the United States in 2003. Canada found 19 native cattle with BSE between 2003 and 2010 (and imported a case from the United Kingdom in 1993). In spite of encouraging epidemiologic studies that failed to implicate exposure to scrapie or CWD agents in human TSEs, it seems prudent to avoid exposing children to meat and other products likely to be contaminated with any TSE agent.

The safety of human blood, blood components, and plasma derivatives in the United States and Canada is protected by deferring those donors with histories suggesting an increased risk of TSEs: persons treated with cadaveric pituitary hormones (no longer used) or dura mater allografts, patients with a family history of CJD (unless sequencing shows that the TSE-affected blood relative or the donor has revealed no TSE-related mutation in either PRNP gene), and persons who spent substantial periods of time in specified countries during years when BSE was prevalent. Persons transfused with blood in the United Kingdom and France after 1988 should be deferred from donating blood (similar deferral policies are in place for donors of human cells and tissues). U.K. authorities have warned persons treated with U.K.-sourced pooled coagulation factor concentrates or antithrombin between 1989 and 2001 that they may be “at risk of vCJD for public health purposes” and that “special infection control precautions” apply to them.

In principle, it would be better to identify the few blood and tissue donors actually infected with a TSE rather than deferring all those at increased risk of exposure, because most of them are unlikely to have been infected. Accordingly, antemortem donor screening tests that might identify persons with preclinical TSE infections are currently under development but have not been clinically validated. Another attractive approach would be to remove TSE agents from blood. Along these lines, a committee of expert advisors to the U.K. government recommended considering the use of an investigational device to filter red cells intended to transfuse children, because some unknown but possibly substantial number of U.K. blood donors might be incubating vCJD; authorities in the United Kingdom (and Ireland) evaluated, but have not adopted, that advice.

Standard precautions should be used to handle all human tissues, blood, and body fluids. Materials and surfaces contaminated with tissues or fluids from patients suspected of having CJD must be treated with great care. Whenever possible, discard contaminated instruments
by careful packaging and incineration. Contaminated tissues and bio-
logic products probably cannot be completely freed of infectivity
without destroying their structural integrity and biologic activity;
therefore, the medical and family histories of individual tissue donors
should be carefully reviewed to exclude a diagnosis of TSE. Histo-
pathologic examination of brain tissues of cadaveric donors and testing
for abnormal PrP might be performed where feasible to provide an
additional assurance of safety. Although no method of sterilization can
be relied on to remove all infectivity from contaminated surfaces,
exposures to moist heat, sodium hydroxide, chlorine bleach, concen-
trated formic acid, acidified detergent, and guanidine salts markedly
reduced infectivity in experimental studies.

Bibliography is available at Expert Consult.
Parasites are divided into two main groups taxonomically: protozoans, which are unicellular, and helminths, which are multicellular. Chemo- therapeutic agents appropriate for 1 group may not be appropriate for the other, and not all drugs are readily available (Table 279-1). Some drugs are available only from the manufacturer, some are not available in the United States, and some are available through the Centers for Disease Control and Prevention (CDC). Availability of drugs can be ascertained by contacting the Parasitic Diseases Public Inquiries Branch (1-404-718-4745; e-mail INTER REF chagas@cdc.gov). For after-hours emergencies, practitioners can contact the CDC Emergency Operations Center (770-488-7100) and ask for the on-call parasitic diseases physician. For assistance in the management of malaria, healthcare should call the CDC Malaria Hotline: 770-488-7788 or 855-856-4713 toll-free (M-F, 9 AM-5 PM, Eastern time). For emergency consultation after hours, clinicians can phone 770-488-7100 and request to speak with a CDC Malaria Branch clinician.

SELECTED ANTIPARASITIC DRUGS FORPROTOZOANS
Nitoxanide (Alinia)
Nitoxanide is a nitrothiazole benzamide, initially developed as a veterinary anthelminthic. Nitoxanide inhibits pyruvate-ferrodoxin oxidoreductase, which is an enzyme necessary for anaerobic energy metabolism. In humans, nitoxanide is effective against many protozoans and helminths. Nitoxanide is approved for the treatment of diarrhea caused by Cryptosporidium species in children 1-11 yr of age and by Giardia intestinalis in children 1 yr of age and older.

Nitoxanide is available as an oral suspension, which has a pink color and strawberry flavor. The bioavailability is doubled with food. The drug is well absorbed from the gastrointestinal tract. One third is excreted in urine, and two thirds is excreted in feces as the active metabolite, tizoxanide. Although in vitro metabolism studies have not demonstrated cytochrome P450 enzyme effects, no pharmacokinetic studies have been performed yet in patients with compromised renal or hepatic function. In addition, no studies have been performed in pregnant or lactating women. Common adverse effects include abdominal pain, diarrhea, and nausea. Rare side effects include anorexia, flatulence, increased appetite, fever, pruritus, and dizziness. Intriguingly, nitoxanide has activity against both hepatitis C and rotavirus, although the use of the agent against these viruses is investigational.

Tinidazole (Tindamax)
Tinidazole is a synthetic nitroimidazole with a chemical structure similar to metronidazole. It is FDA approved for treatment of trichomoniasis and for giardiasis and amebiasis in children 3 yr of age and older. In the treatment of giardiasis, it has the advantages of very few side effects and only requiring a single dose. Its mechanism of action against Trichomonas may be secondary to the generation of free nitro radicals by the protozoan. The mechanism of action against Giardia lamblia and Entamoeba histolytica is unknown. After oral administration, tinidazole is rapidly and completely absorbed and distributes into almost all tissues and body fluids, including crossing the blood–brain barrier and placental barrier. It is excreted via urine and feces. Hemodialysis increases clearance of drug. No studies have been performed for patients undergoing peritoneal dialysis or for patients with compromised hepatic function. Tinidazole carries a pregnancy category C classification and can be detected in breast milk. Breastfeeding should be interrupted during treatment and for 3 days after treatment.

Atovaquone/Proguanil (Malarone)
Atovaquone is a hydroxynaphthoquinone and has been used in the past predominantly against Pneumocystis pneumonia in AIDS patients. Its mechanism of action is via disruption of mitochondria membrane potential through interaction with cytochrome B. Atovaquone can also effectively inhibit liver stages of all Plasmodium species.

Proguanil is approved for use in the United States. Its mechanism of action is inhibition of the parasite dihydrofolate reductase enzyme by the active form, cycloguanil. When used alone, it has poor efficacy for prophylaxis.

Proguanil acts in synergy with atovaquone on the cytochrome B enzyme in Plasmodia mitochondria. The exact mechanism of synergy is unknown. In 2000, the FDA approved atovaquone/proguanil for the prevention and treatment of acute, uncomplicated Plasmodium falciparum malaria. Atovaquone alone and in combination with proguanil is the only drug to completely inhibit the liver stage, which provides the advantage of only needing to use the drug for 7 days after departing a malaria-endemic area (compared to several weeks).

Two double-blind, randomized clinical trials assessing malaria prophylaxis demonstrated that atovaquone/proguanil was at least comparable to (and perhaps better than) chloroquine plus proguanil, and that atovaquone/proguanil was comparable to mefloquine. Atovaquone/proguanil was better tolerated than chloroquine plus proguanil and mefloquine. Atovaquone/proguanil treatment of acute uncomplicated P. falciparum infection has demonstrated higher or comparable cure rates when compared with other P. falciparum treatment drugs. Compared with other antimalarial treatment therapies, atovaquone/proguanil treatment has the highest cost.
## Table 279-1 Drugs for Parasitic Infections

Parasitic infections are found throughout the world. With increasing travel, immigration, use of immunosuppressive drugs, and the spread of AIDS, physicians anywhere may see infections caused by previously unfamiliar parasites. The table below lists first-choice and alternative drugs for most parasitic infections.

---

1 For treatment of keratitis caused by Acanthamoeba, concurrent topical use of 0.1% propamidine isethionate (Brolene) plus neomycin-polymyxin B-gramicidin ophthalamic solution has been successful (Hargrave SL, et al: Ophthalmol 106:952, 1999). In some European countries, propamidine is not available and hexamidine (Desmodine) has been used (Seal DV, Eye 17:893, 2003). In addition, 0.02% topical polyhexamethylene biguanide (PHMB) and/or chlorhexidine has been used successfully in a large number of patients (Tabin G, et al: Cornea 20:757, 2001; Wysenbeek YS, et al: Cornea 19:464, 2000). PHMB is available from Leiter’s Park Avenue Pharmacy, San Jose, CA (800-292-6773, www.leiterrx.com). The combination of chlorhexidine, natamycin (pimaricin), and debridement also has been successful (Kitagawa K, et al: Jpn J Ophthalmol 47:616, 2003).

2 The drug is not available commercially, but as a service can be compounded by Panorama Compounding Pharmacy, 6744 Balboa Blvd, Van Nuys, CA 91406 (201-688-6181).

3 Treatment should be followed by a course of iodoquinol or paromomycin in the dosage used to treat asymptomatic amebiasis.

4 Nitazoxanide is FDA approved as a pediatric oral suspension for treatment of Cryptosporidium in immunocompetent children younger than 12 yr old and for Giardia (Med Lett 2003:45:29). It may also be effective for mild to moderate amebiasis (Diaz E, et al: Am J Trop Med Hyg 68:384, 2003). Nitazoxanide is available in 500 mg tablets and an oral suspension; it should be taken with food.

5 A nitrimidazole similar to metronidazole, tinidazole was recently approved by the FDA and appears to be as effective and better tolerated than metronidazole. It should be taken with food to minimize GI adverse effects. For children and patients unable to take tablets, a pharmacist may crush the tablets and mix them with cherry syrup (Humco, and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use. Omidazole, a similar drug, is also used outside the United States.

7 An approved drug, but considered investigational for this condition by the FDA.

8 Strains of Acanthamoeba isolated from fatal granulomatous amebic encephalitis are usually susceptible in vitro to pentamidine, ketoconazole, flucytosine, and (less so) to amphotericin B. Chronic Acanthamoeba meningitis has been successfully treated in 2 children with a combination of oral trimethoprim-sulfamethoxazole, rifampin, and ketoconazole (Singhal T, et al: Pediatr Infect Dis J 20:623, 2001), and in an AIDS patient with fluconazole, sulfadiazine, and pyrimethamine combined with surgical resection of the CNS lesion (Seijo Martinez M, et al: J Clin Microbiol 38:3892, 2000). Disseminated cutaneous infection in an immunocompromised patient has been treated successfully with IV pentamidine isethionate, topical chlorhexidine, and 2% ketoconazole cream, followed by oral itraconazole (Slater CA, et al: N Engl J Med 318:85, 1994).

---

1 A free-living leptomyxid ameba that causes subacute to fatal granulomatous CNS disease. Several cases of Balamuthia encephalitis have been successfully treated with flucytosine, pentamidine, fluconazole, and sulfadiazine plus either azithromycin or clarithromycin (phenothiazines were also used) combined with surgical resection of the CNS lesion (Deets TR, et al.; Clin Infect Dis 57:1304, 2003; Jung S, et al.; Arch Pathol Lab Med 128:466, 2004). Miltefosine is another option currently being evaluated but it is not approved for any indication in the United States at this time. Case reports and in vitro data suggest it may have some antiamebic activity.

2 A free-living ameba not previously known to be pathogenic to humans. It has been successfully treated with azithromycin, IV pentamidine, itraconazole, and sulfadiazine; or clindamycin, IV quinine, and oral rifampin. Amphotericin B has also been used. The role of surgical intervention remains controversial.

3 Exchange transfusion has been used in severely ill patients and those with high (>10%) parasitemia (Hatcher JC, et al; Clin Infect Dis 32:1117, 2001). In patients who were not severely ill, combination therapy with atovaquone and azithromycin was as effective as clindamycin and quinine and may have been better tolerated (Krause PJ, et al.; N Engl J Med 343:1454, 2000). Highly immunosuppressed patients should be treated for a minimum of 6 wk and at least 2 wk past the last positive smear (PJ Krause et al., Clin Infect Dis 2008; 46:370). High doses of azithromycin (600-1,000 mg) have been used in combination with atovaquone for the treatment of immunocompromised patients (LM Weiss et al., N Engl J Med 2001; 344:773). Resistance to atovaquone plus azithromycin has been reported in immunocompromised patients treated with a single subcutaneous course of this regimen (GP Wormser et al., Clin Infect Dis 2010, 50:381).

15No drugs have been consistently demonstrated to be effective. The combination of albendazole 37 mg/kg/d PO and high-dose steroids has been used successfully (JM Peters et al., Pediatrics 2012; 129:e806; S Haider, Emerg Infect Dis 2012; 18:347). Albendazole 25 mg/kg/d PO × 20 d started as soon as possible (up to 3 d after possible infection) might prevent clinical disease and is recommended for children with known exposure, such as in the setting of ingestion of raccoon stool or contaminated soil (WJ Murray and KR Kazacos, Clin Infect Dis 2004, 39:1484). Mebendazole, levamisole, or ivermectin could be tried if albendazole is not available. Ocular baylisascariasis has been treated successfully using laser photocoagulation therapy to destroy the intraretinal larvae.

17Nitazoxanide has not consistently been shown to be superior to placebo in HIV-infected patients (Amadi B, et al: Lancet 360;1375, 2002). For HIV-infected patients, potent antiretroviral therapy (ART) is the mainstay of treatment. Nitazoxanide (treatment duration of 5-21 days), paromomycin, or a combination of paromomycin and azithromycin may be tried to decrease diarrhea and recalcitrant malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis (B Pansenburg et al., Expert Rev Anti Infect Ther 2009; 7:385).

²¹Treatment of choice is slow extraction of worm combined with wound care (MMWR Morb Mortal Wkly Rep 2011; 60:1450). 10 days’ treatment with metronidazole 250 mg tid in adults and 25 mg/kg/day in 3 doses in children is not curative, but decreases inflammation and facilitates removal of the worm. Mebendazole 400-800 mg/day × 6 days has been reported to kill the worm directly.

²²Since all family members are usually infected, treatment of the entire household is recommended.

²³Antihistamines or corticosteroids may be required to decrease allergic reactions due to disintegration of microfilariae from treatment of filarial infections, especially those caused by Loa loa. Endosymbiotic Wolbachia bacteria may have a role in filarial development and host response, and may represent a new target for therapy. Treatment with doxycycline 100 or 200 mg/day × 4-6 wk in lymphatic filariasis and onchocerciasis has resulted in substantial loss of Wolbachia with a subsequent block of microfilariae production and absence of microfilaria when followed for 24 mo after treatment (Hoerauf A, et al: Med Microbiol Immunol 192:211; 2003; Hoerauf A, et al: BMJ 326.207, 2003).

²⁴Most symptoms caused by adult worm. Single-dose combination of albendazole (400 mg) with either ivermectin (200 µg/kg) or diethylcarbamazine (6 mg/kg) is effective for reduction or suppression of Wuchereria bancrofti microfilaria but does not kill the adult forms (Addiss D, et al: Cochrane Database Syst Rev 2004;CD003753).

²⁵For patients with microfilaria in the blood, Medical Letter consultants would start with a lower dosage and scale up: day 1, 50 mg; day 2, 50 mg tid; day 3, 100 mg tid; day 4-14, 6 mg/kg in 3 doses (for Loa loa day 4-14, 9 mg/kg in 3 doses). Multidose regimens have been shown to provide more rapid reduction in microfilaria than single-dose diethylcarbamazine, but microfilaria levels are similar 6-12 mo after treatment (Andrade LD, et al: Trans R Soc Trop Med Hyg 89:319, 1995; Simonsen PE, et al: Am J Trop Med Hyg 53:207, 1995). A single dose of 6 mg/kg is used in endemic areas for mass treatment (Piguet-Cosa-Silva J, et al: Trans R Soc Trop Med Hyg 90:192, 1996; Noroe J, et al: Trans R Soc Trop Med Hyg 91:78, 1997).

²⁷Diethylcarbamazine has no effect. Ivermectin 200 µg/kg once has been effective.

²⁸Diethylcarbamazine is potentially curative because of activity against both adult worms and microfilariae. Ivermectin is only active against microfilariae. (The Medical Letter: Drugs for parasitic infections, ed 2, 2010).

²⁹Relapse occurs and can be treated with diethylcarbamazine.

³⁰Annual treatment with ivermectin, 150 µg/kg, can prevent blindness from ocular onchocerciasis (Mabey D, et al: Ophthalmology 103:1001, 1996). Diethylcarbamazine should not be used for treatment of this disease.

31Unlike infections with other flukes, *Fasciola hepatica* infections may not respond to praziquantel. Triclabendazole (Egaten, Novartis) may be safe and effective but data are limited (Graham CS, et al: *Clin Infect Dis* 33:1, 2001). It is available from Victoria Pharmacy, Zurich, Switzerland (www.pharmaworld.com; 41-1-211-24-32) and should be given with food for better absorption. A single study has found that nitazoxanide has limited efficacy for treating fascioliasis in adults and children (Favennec L, et al: *Aliment Pharmacol Ther* 17:265, 2003).

34Triclabendazole may be effective in a dosage of 5 mg/kg PO once/day × 3 days or 10 mg/kg bid + 1 day (Calvopiña M, et al: *Trans R Soc Trop Med Hyg* 92:566, 1998). See footnote 31 for availability.

36Not absorbed; may be useful for treatment of giardiasis in pregnancy.

- 2.3 mg/kg IV or IM daily or every 2 days × 4-7 doses

or Paromomycin
- Topically 2x/day × 10-20 days
- Topically 2x/day × 10-20 days

---

Consultation with physicians experienced in management of this disease is recommended. To maximize effectiveness and minimize toxicity, the choice of drug, dosage and duration of therapy should be individualized based on the region of disease acquisition, likely infecting species, number, significance and location of lesions, and host factors such as immune status (HW Murray, Lancet 2005; 366:1561). Some of the listed drugs and regimens are effective only against certain Leishmania species/strains and only in certain areas of the world (S Sundar and J Chakravarty, Expert Opin Pharmacother 2013; 14:53). Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired. Visceral leishmaniasis is most commonly caused by the Old World species Leishmania donovani (kala-azar) and Leishmania infantum and the New World species. Leishmania chagasi. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired. May be repeated or continued; a longer duration may be needed for some patients (Henwalit BL: Lancet 354:1191, 1999).

Three lipid formulations of amphotericin B have been used for treatment of visceral leishmaniasis. Largely based on clinical trials in patients infected with Leishmania infantum, the FDA approved liposomal amphotericin B (AmBisome) for treatment of visceral leishmaniasis (Meyhoff A, Clin Infect Dis 1999;28:42). Amphotericin B lipid complex (Abelcet) and amphotericin B cholesteryl sulfate (Amphotec) have also been used with good results but are considered investigational for this condition by the FDA.

The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/day (days 1-5) and 4 mg/kg/day on days 10, 17, 24, 31, and 38. The relapse rate is high, maintenance therapy may be indicated, but there is no consensus as to dosage or duration. (Russo R, Nigro LC, Minniti S, et al: Visceral leishmaniasis in HIV infected patients: treatment with high dose liposomal amphotericin B (AmBisome), J Infect 32:133-137, 1996).

For treatment of kala-azar in adults in India, oral miltefosine 100 mg/day (–205 mg/kg/day) for 28 days was 97% effective after 6 mo (Jha TK, et al: N Engl J Med 341:1795, 1999; Sangraula H, et al: J Assoc Physicians India 51:686, 2003). Gastrointestinal adverse effects are common, and the drug is contraindicated in pregnancy. The dose of miltefosine in an open-label trial in children in India was 2.5 mg/kg/day × 28 days (Bhattacharya SK, et al: Clin Infect Dis 38:217, 2004). Miltefosine (Impavid) is available from the manufacturer (Zentaris, Frankfurt, Germany at impavid@zentaris.de).

Cutaneous infection is most commonly caused by the Old World species Leishmania major and Leishmania tropica and the New World species Leishmania mexicana, Leishmania (Viannia) braziliensis and others. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired.

In a placebo-controlled trial in patients 12 yr old and older, oral miltefosine was effective for the treatment of cutaneous leishmaniasis caused by Leishmania (Viannia) panamensis in Colombia but not L. (V.) braziliensis in Guatemala at a dosage of about 2.5 mg/kg/day for 28 days. “Motion sickness,” nausea, headache and increased creatinine were the most frequent adverse effects (Soto J, et al: Clin Infect Dis 38:1266, 2004). See footnote 44 regarding miltefosine availability. For treatment of L. major cutaneous lesions, a study in Saudi Arabia found that oral fluconazole, 200 mg once/day × 6 wk, appeared to speed healing (Alrghy AA, et al: N Engl J Med 346:891, 2002).

At this dosage pentamidine has been effective against leishmaniasis in Colombia where the likely organism was L. (V.) panamensis (Soto-Mancipe J, et al: Clin Infect Dis 16:417, 1993; Soto J, et al: Am J Trop Med Hyg 50:107, 1994). Its effect against other species is not well studied.

Topical paromomycin/12% methylbenzenzethionium chloride (Leschutan) in soft white paraffin for topical use has been reported to be partially effective in some patients against cutaneous leishmaniasis due to L. major in Israel and against L. mexicana and L. (V.) braziliensis in Guatemala, where mucosal spread is very rare (Arana BA, et al: Am J Trop Med Hyg 65:466, 2001). The methylbenzenzethionium is irritating to the skin; lesions may worsen before they improve.

#### Malaria, treatment of (Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax, and Plasmodium malariae)

**P. falciparum⁴⁴ acquired in areas of chloroquine resistance**

**Oral⁴⁵**

| Drugs of choice: | Atovaquone/proguanil⁵⁶ | 2 adult tabs PO bid or 4 adult tabs PO once daily × 3 days | <5 kg: not indicated |
| or | Quinine sulfate | 650 mg PO every 8 hr × 3-7 days⁵⁷ | 5-8 kg: 2 pediatric tabs PO once/day × 3 days |
| or | Doxycycline | 100 mg PO bid × 7 days | 9-10 kg: 3 pediatric tabs PO once/day × 3 days |
| or | Tetracycline | 250 mg PO qid × 7 days | 11-20 kg: 1 adult tab PO once/day × 3 days |
| or | Clindamycin | 20 mg/kg/day PO in 3 doses × 7 days⁵⁶ | 21-30 kg: 2 adult tabs PO once/day × 3 days |
| or | 31-40 kg: 3 adult tabs PO once/day × 3 days | >40 kg: 4 adult tabs PO once/day × 3 days |

**Uncomplicated or mild malaria may be treated with oral drugs.**

**Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; atovaquone 250 mg/proguanil 100 mg) and pediatric tablets (Malarone Pediatric, atovaquone 62.5 mg/proguanil 25 mg). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown and use is generally not recommended. In a few small studies outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (B Paternak et al., Arch Intern Med 2011; 171:259; AK Bogdill et al., Am J Trop Med Hyg 2007; 76:208). The drug should not be given to patients with severe renal impairment (creatinine clearance <30 mL/min). There have been isolated case reports of resistance in P. falciparum in Africa, but Medical Letter consultants do not believe there is a high risk for acquisition of Malarone-resistant disease (E Schwartz et al., Clin Infect Dis 2003; 37:450; A Farnert et al., BMJ 2003; 326:628; S Kuhn et al., Am J Trop Med Hyg 2005; 72:407; CT HAPP et al., Malar J 2006; 5:8).**

**In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 days.**

**Although approved for once daily dosing, Medical Letter consultants usually divide the dose in 2 to decrease nausea and vomiting.**

**For use in pregnancy.**

---

⁴⁹Mucosal infection is most commonly due to the New World species L. (V.) braziliensis, L. (V.) panamensis, or L. (V.) guyanensis. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired.

⁵⁰For infestation of eyelashes with Phthirus pubis lice, use petrolatum; TMP-SMX has also been used (Meinking TL: Curr Probl Dermatol 24:157, 1996). For pubic lice, treat with 5% permethrin or ivermectin as for scabies. TMP-SMX has also been effective together with permethrin for head lice (Hipolito RB, et al: Pediatrics 107:E30, 2001).

⁵²A second application is recommended 1 wk later to kill hatching progeny. Some lice are resistant to pyrethrins and permethrin (Meinking et al: Arch Dermatol 2002;138:220).

⁵³Ivermectin is effective against adult lice but has no effect on nits (Jones KN, JC English III: Clin Infect Dis 36:1355, 2003).

⁵⁴Chloroquine-resistant P. falciparum occurs in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, Saudi Arabia, and Iran). For treatment of multidrug-resistant P. falciparum in Southeast Asia, especially Thailand, where resistance to mefloquine is frequent, atovaquone/proguanil, artesunate plus mefloquine, or artemether plus mefloquine may be used (Luxemburger JC, et al.: Trans R Soc Trop Med Hyg 88:213, 1994; Karbwang J, et al.: Trans R Soc Trop Med Hyg 89:296, 1995).

⁵⁵Uncomplicated or mild malaria may be treated with oral drugs.

### Drug of choice:

- Chloroquine phosphate
- Mefloquine
- Quinine sulfate

### Alternatives:

- Doxycycline
- Primaquine
- Quinidine gluconate
- Quinidine dihydrochloride

### Parenteral (severe infection; chloroquine-sensitive and resistant)

### Drugs of choice:

- Quinidine gluconate
- Quinidine dihydrochloride

### Alternatives:

- Chloroquine phosphate
- Mefloquine
- Doxycycline
- Primaquine

---

84 At this dosage, adverse effects including nausea, vomiting, diarrhea, dizziness, disturbed sense of balance, toxic psychosis, and seizures can occur. Mefloquine should not be used for treatment of malaria in pregnancy unless there is no other treatment option because of increased risk for stillbirth (Nosten F, et al: *Clin Infect Dis* 28:808, 1999). It should be avoided for treatment of malaria in persons with active depression or with a history of psychosis or seizures and should be used with caution in persons with psychiatric illness. Mefloquine can be given to patients taking β-blockers if they do not have an underlying arrhythmia; it should not be used in patients with conduction abnormalities. Mefloquine should not be given together with quinine, quinidine, or halofantrine, and caution is required in using quinine, quinidine, or halofantrine to treat patients with malaria who have taken mefloquine for prophylaxis. Resistance to mefloquine has been reported in some areas, such as the Thailand-Myanmar and Thailand-Cambodia borders and in the Amazon basin, where 25 mg/kg should be used. In the United States, a 250 mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275 mg tablet contains 250 mg base.

85 *P. falciparum* with resistance to mefloquine is a significant problem in the malarious areas of Thailand and in areas of Myanmar and Cambodia that border on Thailand. It has also been reported on the borders between Myanmar and China, Laos and Myanmar, and in Southern Vietnam. In the United States, a 250 mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275 mg tablet contains 250 mg base.

86 *P. vivax* with decreased susceptibility to chloroquine is a significant problem in Papua New Guinea and Indonesia. There are also a few reports of resistance from Myanmar, India, the Solomon Islands, Vanuatu, Guyana, Brazil, Colombia, and Peru.

87 Primquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase (G6PD). This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Primquine should not be used during pregnancy.

88 If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

90 Continuous ECG, blood pressure, and glucose monitoring are recommended, especially in pregnant women and young children. For problems with quinidine availability, call the manufacturer (Eli Lilly, 800-545-5979) or the CDC Malaria Hotline (770-488-7788). Quinidine may have greater antimalarial activity than quinine. The loading dose should be decreased or omitted in those patients who have received quinine or mefloquine. If more than 48 hr of parenteral treatment is required, the quinine or quinidine dose should be reduced by 30-50%.

</table>

<sup>64</sup> Oral artemesunate is not available in the United States; the IV formulation is available through the CDC Malaria branch under an investigational new drug (IND) for patients with severe disease who do not have timely access or cannot tolerate, or fail to respond to IV quinidine (Med Lett Drugs Ther 2008; 50:37). To avoid development of resistance, adults treated with artemesunate must also receive oral treatment doses of either atovaquone/proguanil, doxycycline, clindamycin, or mefloquine; children should take either atovaquone/proguanil, clindamycin, or mefloquine (F Nosten et al., Lancet 2005; 366:717; PE Duffy and CH Sibley, Lancet 2005;366:1908). Reduced susceptibility to artemesunate characterized by slow parasitic clearance has been reported in Cambodia (WO Rogers et al., Malar J 2009; 8:10; AM Dundorp et al., N Engl J Med 2009, 361:455).

<sup>65</sup> No drug regimen guarantees protection against malaria. If fever develops within a year (particularly within the first 2 mo) after travel to malarious areas, travelers should be advised to seek medical attention. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis (Med Lett 45:41, 2003). Malaria in pregnancy is particularly serious for both mother and fetus; therefore, prophylaxis is indicated if exposure cannot be avoided. See also footnote 64.

<sup>66</sup> In pregnancy, chloroquine prophylaxis has been used extensively and safely.

<sup>67</sup> For prevention of attack after departure from areas where *P. vivax* and *P. ovale* are endemic, which includes almost all areas where malaria is found (except Haiti), some experts prescribe in addition primaquine phosphate 30 mg base/day or, for children, 0.6 mg base/kg/day during the last 2 wk of prophylaxis. Others prefer to avoid the toxicity of primaquine and rely on surveillance to detect cases when they occur, particularly when exposure was limited or doubtful. See also footnote 64.

<sup>68</sup> Beginning 1-2 wk before travel and continuing weekly for the duration of stay and for 4 wk after leaving malarious zone. Most adverse events occur within 3 doses. Some Medical Letter consultants favor starting mefloquine 3 wk prior to travel and monitoring the patient for adverse events; this allows time to change to an alternative regimen if mefloquine is not tolerated. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water. For pediatric doses less than ½ tablet, it is advisable to have a pharmacist crush the tablet, estimate doses by weighing, and package them in gelatin capsules. There are no data for use in children weighing <5 kg, but based on dosages in other weight groups, a dose of 5 mg/kg can be used.

<sup>69</sup> Beginning 1-2 days before travel and continuing for the duration of stay and for 1 wk after leaving. In 1 study of malaria prophylaxis, atovaquone/proguanil was better tolerated than mefloquine in nonimmune travelers (D Overbosch et al., Clin Infect Dis 33:1015, 2001).

<sup>70</sup> Mefloquine has not been approved for use during pregnancy. However, it has been reported to be safe for prophylactic use during the 2nd or 3rd trimester of pregnancy and possibly during early pregnancy as well. Mefloquine is not recommended for patients with cardiac conduction abnormalities, and patients with a history of depression, seizures, psychosis, or psychiatric disorders should avoid mefloquine prophylaxis. Resistance to mefloquine has been reported in some areas, such as the Thailand-Myanmar and Thailand-Cambodia borders; in these areas, atovaquone/proguanil or doxycycline should be used for prophylaxis.

<sup>71</sup> Beginning 1-2 days before travel and continuing for the duration of stay and for 4 wk after leaving. Use of tetracyclines is contraindicated in pregnancy and in children younger than 8 yr old. Doxycycline can cause gastrointestinal disturbances, vaginal moniliasis, and photosensitivity reactions.

<sup>72</sup> Studies have shown that daily primaquine beginning 1 day before departure and continued until 3-7 days after leaving the malaria area provides effective prophylaxis against chloroquine-resistant *P. falciparum* (Baird JK, et al., Lancet 2005;366:1908). Reduced susceptibility to primaquine characterized by slow parasitic clearance has been reported in Cambodia (WO Rogers et al., Malar J 2009; 8:10; AM Dundorp et al., N Engl J Med 2009, 361:455).

<sup>73</sup> Studies have shown less efficacy against *P. vivax*. Nausea and abdominal pain can be diminished by taking with food.

<sup>74</sup> A traveler can be given a course of atovaquone/proguanil, mefloquine, or quinine plus doxycycline for presumptive self-treatment of febrile illness. The drug given for self-treatment should be different from that used for prophylaxis. This approach should be used only in very rare circumstances when a traveler cannot promptly get to medical care.

---

\(^{70}\) Ocucal lesions caused by *E. hellem* in HIV-infected patients have responded to fumagillin eye drops prepared from Fumidil-B (bicyclohexyl ammonium fumagillin) used to control a microsporidial disease of honey bees (Diesenhouse MC, Am J Ophthalmol 115:293, 1993), available from Leiter’s Park Avenue Pharmacy (see footnote 1). For lesions caused by *V. corneae*, topical therapy is generally not effective and keratoplasty may be required (Davis RM, et al: Ophthalmology 112:953, 1990).

\(^{78}\) Pneumocystis has been reclassified as a fungus. In severe disease with room air PO₂ ≤70 mm Hg or A-aO₂ gradient ≥35 mm Hg, prednisone should also be used (Gagnon S, et al: N Engl J Med 323:1444, 1990; Caumes E, et al: Clin Infect Dis 18:319, 1994).

</table>

*Primary/secondary prophylaxis in patients with HIV can be discontinued after CD4 count increases to >200 x 10⁹/L for longer than 3 mo.*

*An alternative trimethoprim-sulfamethoxazole regimen is 1 DS tab 3x/wk. Weekly therapy with sulfadoxine 500 mg/pyrimethamine 25 mg/leucovorin 25 mg was effective Pneumocystis carinii pneumonia (PCP) prophylaxis in liver transplant patients (Torre-Cisneros J, et al: Clin Infect Dis 29:771, 1999).*

*Plus leucovorin 25 mg with each dose of pyrimethamine.*

*In some cases, treatment may need to be repeated in 10-14 days. BJ Currie and JS McCarthy, N Engl J Med 2010; 362:717. A second ivermectin dose taken 2 wk later increased the cure rate to 95%, which is equivalent to that of 5% permethrin (V Usha et al., J Am Acad Dermatol 2000; 42:236). Ivermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (P del Giudice, Curr Opin Infect Dis 2004; 15:123).*

*Lindane (γ-benzene hexachloride; Kwell) should be reserved as a second-line agent. The FDA has recommended it should not be used for immunocompromised patients, young children, the elderly, and patients who weigh <50 kg.*

*Invermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (del Giudice P: Curr Opin Infect Dis 15:123, 2004). The safety of oral ivermectin in pregnancy and young children has not been established.*

</tbody>
</table>

90Oxamniquine has been effective in some areas in which praziquantel is less effective (Stelma FF, et al: J Infect Dis 176:304, 1997). Oxamniquine is contraindicated in pregnancy.
91In East Africa, the dose should be increased to 30 mg/kg, and in Egypt and South Africa to 30 mg/kg/day × 2 days. Some experts recommend 40-60 mg/kg over 2-3 days in all of Africa (Shekhar KC: Drugs 42:379, 1991).
92In immunocompromised patients or disseminated disease, it may be necessary to prolong or repeat therapy, or to use other agents. Veterinary parenteral and enema formulations of ivermectin have been used in severely ill patients unable to take oral medications (Chioldini PL, et al: Lancet 355:43, 2000; Orem J, et al: Clin Infect Dis 37:152, 2003; Tarr PE: Am J Trop Med Hyg 68:453, 2003).
93Albendazole must be taken with food; a fatty meal increases oral bioavailability.
95Patients may benefit from surgical resection or percutaneous drainage of cysts. Praziquantel is useful preoperatively or in case of spillage of cyst contents during surgery. Percutaneous aspiration-injection-reaspiration (PAIR) with ultrasound guidance plus albendazole therapy has been effective for management of hepatic hydatid cyst disease (Smego RA Jr, et al: Clin Infect Dis 37:1073, 2003).
96Surgical excision is the only reliable means of cure. Reports have suggested that in nonresectable cases use of albendazole or mebendazole can stabilize and sometimes cure infection (Craig P: Curr Opin Infect Dis 16:437, 2003).
97Initial therapy for patients with inflamed parenchymal cisticercosis should focus on symptomatic treatment with antiseizure medication. Treatment of parenchymal cisticerci with albendazole or praziquantel is controversial (Maguire JM: N Engl J Med 350:215, 2004). Patients with live parenchymal cysts who have seizures should be treated with albendazole together with steroids (6 mg dexamethasone or 40-60 mg prednisone daily) and an antiseizure medication (Garcia HH, et al: N Engl J Med 350:249, 2004). Patients with subarachnoid cysts or giant cysts in the tissues should be treated for at least 30 days (Praoão JV, et al: N Engl J Med 345:879, 2001). Surgical intervention or CSF diversion is indicated for obstructive hydrocephalus; prednisone 40 mg/day may be given with surgery. Arachnoiditis, vasculitis, or cerebral edema is treated with prednisone 60 mg/day or dexamethasone 4-6 mg/day together with albendazole or praziquantel (White Jr AC: Annu Rev Med 51:187, 2000). Any cisticercoidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when corticosteroids are used. An ophthalmic exam should always precede treatment to rule out intraocular cysts.

<sup>98</sup>To ocular toxoplasmosis with macular involvement, corticosteroids are recommended in addition to antiparasitic therapy for an antiinflammatory effect.

<sup>99</sup>To treat CNS toxoplasmosis in HIV-infected patients, some clinicians have used pyrimethamine 50-100 mg/day (after a loading dose of 200 mg) with sulfadiazine and, when sulfonamide sensitivity developed, have given clindamycin 1.8-2.4 g/day in divided doses instead of the sulfonamide. Atovaquone plus pyrimethamine appears to be an effective alternative in sulfadiazine-intolerant patients (Chirgin K, et al. Clin Infect Dis 34:1243, 2002). Treatment is followed by chronic suppression with lower-dosage regimens of the same drugs. For primary prophylaxis in HIV patients with <100 x 10<sup>9</sup>/L CD4 cells, either trimethoprim-sulfamethoxazole, pyrimethamine with dapsone, or atovaquone with or without pyrimethamine can be used. Primary or secondary prophylaxis may be discontinued when the CD4 count increases >100 x 10<sup>9</sup>/L.

<sup>100</sup>Women who develop toxoplasmosis during the 1st trimester of pregnancy can be treated with spiramycin (3-4 g/day). After the 1st trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. If transmission has occurred in utero, therapy with pyrimethamine and sulfadiazine should be started (Montoya JG, Liesenfeld O: Lancet 363:1965, 2004). Pyrimethamine is a potential teratogen and should be used only after the 1st trimester.

<sup>101</sup>Plus leucovorin 10-25 mg with each dose of pyrimethamine.

<sup>102</sup>Congenitally infected newborns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about 1 yr (Remington JS, Klein JO, editors: Infectious disease of the fetus and newborn infant, ed 5, Philadelphia, 2001, WB Saunders, p. 290).

<sup>103</sup>Sexual partners should be treated simultaneously. Metronidazole-resistant strains have been reported and can be treated with higher doses of metronidazole (2-4 g/day x 7-14 days) or with tinidazole (Hager WD: Sex Transm Dis 31:343, 2004).

<sup>105</sup>The addition of γ-interferon to nifurtimox for 20 days in experimental animals and in a limited number of patients appears to shorten the acute phase of Chagas disease (McCabe RE, et al. J Infect Dis 163:912, 1991).
**SELECTED ANTIPARASITIC DRUGS FOR HELMINTHS**

**Albendazole (Albenza)**

Albendazole is a benzimidazole carbamate structurally related to mebendazole and has similar anthelmintic activity. Its absorption from the gastrointestinal tract is poor but improved with a concomitant high-fat meal. Albendazole sulfoxide, the principal metabolite with anthelmintic activity, has a plasma half-life of 8.5 hr. It is widely distributed in the body, including the bile and cerebrospinal fluid. It is eliminated by bile. Albendazole is FDA approved for treatment of neurocysticercosis and hydatid diseases (Echinococcus granulosus). It is not FDA approved but is used for Ancylostoma caninum, ascariasis, Chinese liver fluke, cutaneous larva migrans, pinworms, filariasis, gnathostomiasis, hookworms, microsporidiosis, and visceral larva migrans. Albendazole is generally well tolerated. Common adverse effects include headache, nausea, vomiting, and abdominal pain. Serious adverse effects include elevated liver enzymes and leukopenia, which have occurred in a few patients with treatment of hydatid disease. Rare adverse effects include acute renal failure, pancytopenia, granulocytopenia, and thrombocytopenia.

**Ivermectin (Stromectol, Mectizan)**

Ivermectin is a semisynthetic derivative of 1 of the avermectins, which is a group of macrocyclic lactones produced by Streptomyces avermitilis. After oral administration, ivermectin has peak plasma concentrations after approximately 4 hr and a plasma elimination half-life of approximately 12 hr. It is excreted as metabolites over a 2 wk period via feces. It is FDA approved for treatment of onchocerciasis and intestinal strongyloidiasis. It may have some effect in treating cutaneous larva migrans, intestinal nematode infections, loiasis, lymphatic filariasis, Mansonella infections, and scabies. Combination therapies of ivermectin with albendazole or diethylcarbamazine are being used to treat lymphatic filariasis. Common adverse events include dizziness, headache, pruritus, and gastrointestinal effects. Serious adverse events include Mazzotti reactions, including arthralgia, synovitis, enlarged lymph nodes, rash, and fever secondary to microfilaria death in patients with onchocerciasis.

**Praziquantel (Biltricide)**

Praziquantel achieves its antiparasitic activity via the pyrazino isoquinoline ring system and was originally synthesized as a potential tranquilizer. After oral administration, praziquantel is rapidly absorbed with peak levels in 1-2 hr and plasma half-life of about 1-3 hr. Elimination via the urine and feces is >80% complete after 24 hr. Praziquantel is metabolized in the liver by the microsomal cytochrome P450 (especially 2B1 and 3A). Bioavailability of praziquantel is increased with concomitant administration of agents that inhibit cytochrome P450. Praziquantel is FDA approved for treatment of Chinese liver fluke, Southeast Asian liver fluke, and schistosomiasis. It is used for treatment of intestinal flukes, North American liver fluke, *Nanophyetus salmincola*, lung fluke, and tapeworm infections but is not FDA approved for these indications. Adverse effects can be seen in 30-60% of patients.
although most are mild and disappear within 24 hr. Common adverse effects include headache, abdominal pain, dizziness, and malaise. Serious but rare adverse effects include arrhythmias, heart block, and convulsions.
Naegleria, Acanthamoeba, Balamuthia, and Sappinia are small, free-living amebas that cause human amebic meningoencephalitis, which has 2 distinct clinical presentations. The more common is an acute, fulminant, and usually fatal amebic meningitis caused by Naegleria that occurs in previously healthy children and young adults. Granulomatous amebic meningoencephalitis, which is caused by Acanthamoeba, Balamuthia, and Sappinia, is a more indolent infection that typically occurs in immunocompromised hosts.

ETIOLOGY
Naegleria is an ameboflagellate that can exist as cysts, trophozoites, and transient flagellate forms. Temperature and environmental nutrient and ion concentrations are the major factors that determine the stage of the ameba. Trophozoites are the only stages that are invasive, although cysts are potentially infective, because they can convert to the vegetative form very quickly under the proper environmental stimuli. Although there are some 30 species of Naegleria, only Naegleria fowleri has been shown to be pathogenic for humans.

Acanthamoeba exist in cyst and motile trophozoite forms; only the trophozoite form is invasive. Cases of Acanthamoeba keratitis usually follow incidents of trivial corneal trauma followed by flushing with contaminated tap water. Infections can also occur among contact lens wearers who come in contact with contaminated water during swimming or using contact lenses cleaned or stored in contaminated tap water. Granulomatous amebic encephalitis from Acanthamoeba occurs worldwide and is associated with an immunocompromising condition such as HIV infection, diabetes mellitus, chronic liver disease, renal failure, immunosuppressive therapy, or radiation therapy.

Balamuthia mandrillaris has been implicated as an etiology of granulomatous amebic encephalitis. Although the clinical presentation is similar to infection with Acanthamoeba, most patients are not immunocompromised.

Other free-living amebas can also cause infection, as illustrated by case reports of Sappinia diploidea granulomatous encephalitis.

EPIDEMIOLOGY
The free-living amebas have a worldwide distribution. Naegleria species have been isolated from a variety of freshwater sources, including ponds and lakes, domestic water supplies, hot springs and spas, thermal discharge of power plants, groundwater, and, occasionally, from the nasal passages of healthy children. Acanthamoeba species have been isolated from soil, mushrooms, vegetables, brackish water, and seawater, as well as most of the freshwater sources for Naegleria. It can also be found in tap water, as chlorine does not kill Acanthamoeba. Balamuthia is present in soil and may be transmitted by inhalation or contamination of preexisting skin lesions.

Naegleria meningoencephalitis has been reported from every continent. Most of the cases occur during the summer months in previously healthy individuals who have a history of swimming in or contact with freshwater before their illness. Only 1-2 cases are reported in the United States per year, but 8 cases were reported in 2001-2002, and 6 cases were reported in 2007. Most of the reports have come from the southern and southwestern states, particularly Florida and Texas, with occasional infections occurring in the Midwest and East. Of note, 2 cases from Louisiana in 2011 were linked to sinus irrigation with neti pots, which contained contaminated tap water.

PATHOGENESIS
The free-living amebas enter the nasal cavity by inhalation or aspiration of dust or water contaminated with trophozoites or cysts. Naegleria gains access to the central nervous system through the olfactory epithelium and migrates via the olfactory nerve to the olfactory bulbs located in the subarachnoid space and bathed by the cerebrospinal fluid (CSF). This space is richly vascularized and is the route of spread to other areas of the central nervous system. Grossly, there is widespread cerebral edema and hyperemia of the meninges. The olfactory bulbs are necrotic, hemorrhagic, and surrounded by a purulent exudate. Microscopically, the gray matter is the most severely affected, with severe involvement in all cases. Fibrinopurulent exudate may be found throughout the cerebral hemispheres, brainstem, cerebellum, and upper portions of the spinal cord. Pockets of trophozoites may be seen in necrotic neural tissue, usually in the perivascular spaces of arteries and arterioles.

The route of invasion and penetration in cases of granulomatous amebic meningoencephalitis caused by Acanthamoeba and Balamuthia may be by direct spread through olfactory epithelium or hematogenous from a primary focus in the skin or lungs. Pathologic examination reveals granulomatous encephalitis, with multinucleated giant cells mainly in the posterior fossa structures, basal ganglia, bases of the cerebral hemispheres, and cerebellum. Both trophozoites and cysts may be found in the central nervous system lesions, primarily located in the perivascular spaces and invading blood vessel walls. The olfactory bulbs and spinal cord are usually spared. The single case of Sappinia encephalitis followed a sinus infection, and evaluation revealed a solitary 2 cm temporal lobe mass with mild ring enhancement.

CLINICAL MANIFESTATIONS
The incubation of Naegleria infection may be as short as 2 days or as long as 15 days. Symptoms have an acute onset and progress rapidly. Infection is characterized by a sudden onset of severe headache, fever, pharyngitis, nasal congestion or discharge, and nausea and vomiting, followed by altered mental status, confusion, somnolence, seizures, and drowsiness. Altered mental status is often a prominent symptom. Headache and fever occur only sporadically, but stiff neck is seen in a majority of cases. Cranial nerve palsies, especially of cranial nerves III and VI, may be present. There is also 1 report of acute hydrocephalus and fever with Balamuthia. Granulomatous amebic meningoencephalitis is usually fatal after 4-6 wk of illness. Results of neuroimaging studies of the brain usually demonstrate multiple low-density lesions resembling infarcts or enhancing lesions of granulomas (Fig. 280-1).

DIAGNOSIS
The CSF in Naegleria infection may mimic that of herpes simplex encephalitis early in the disease and that of acute bacterial meningitis later in the disease, with a neutrophilic pleocytosis, elevated protein level, and hypoglycorrhachia. Motile amebas may be visualized on a wet mount of freshly drawn CSF using Wright or Giemsa stains, but are often mistaken for lymphocytes or macrophages. Because Naegleria are the only amebas that differentiate into the flagellate state in a
hypotonic environment, placing a drop of fresh CSF in 1 mL of distilled water and watching for development of swimming flagellates after 1-2 hr can confirm the diagnosis of *Naegleria*. *Naegleria* can also be grown on a nonnutrient agar plate coated with *Escherichia coli*, on which they feed.

The diagnosis of granulomatous amebic meningoencephalitis relies on the isolation or histologic identification of *Acanthamoeba* trophozoites or cysts from brain tissue specimens. The CSF findings of granulomatous meningoencephalitis reveal lymphocytic pleocytosis, moderately elevated protein, and low glucose concentrations. Motile trophozoites of *Acanthamoeba*, however, are more difficult to isolate than *Naegleria* and the CSF is typically sterile. *Acanthamoeba* may be cultured from the same agar used for growing *Naegleria*, but *Balamuthia* must be grown on mammalian cell cultures. Pediatric cases of *Balamuthia* meningoencephalitis have been diagnosed antemortem by brain biopsy as well as postmortem. Immunofluorescence staining of brain tissue can differentiate *Acanthamoeba* and *Balamuthia*.

**TREATMENT**

*N. fowleri* infection is nearly always fatal, and early recognition and early treatment are crucial to successful therapy. There are several reports of treatment survivors, most of whom recovered fully. *Naegleria* infections have been successfully treated using amphotericin B, either alone or in combination with rifampin, chloramphenicol, fluconazole, or ketoconazole. The early use of dexamethasone may be considered, as steroid treatment was used in the few cases of survivors (as well as nonsurvivors). The optimal duration of treatment is unknown, but at least 10 days of therapy has been used in survivors.

In 2013, the U.S. Centers for Disease Control and Prevention made available miltefosine for the treatment of primary amebic meningoencephalitis. In 2013, two children with *Naegleria* infection survived; both received miltefosine as part of their treatment; one received therapeutic hypothermia.

The optimal therapy for granulomatous amebic meningoencephalitis is also uncertain. Miltefosine has been used to successfully treat patients with *Balamuthia* and disseminated *Acanthamoeba* infections. Strains of *Acanthamoeba* isolated from fatal cases are usually susceptible in vitro to pentamidine, ketoconazole, flucytosine, and less so to amphotericin B. One patient was successfully treated with sulfadiazine and fluconazole, and another was successfully treated with intravenous pentamidine followed by oral itraconazole. *Acanthamoeba* keratitis responds to long courses of topical propamidine–polymyxin B sulfate or topical polyhexamethylene biguanide or chlorhexidine gluconate, and antifungal azoles plus topical steroids. Limited success has been demonstrated in *Balamuthia* infection with systemic azole therapy combined with flucytosine. More recently, the combination of flucytosine, pentamidine, fluconazole, sulfadiazine, a macrolide, and phenothiazines resulted in the survival of 2 patients with *Balamuthia* meningoencephalitis, although both were left with mild neuromotor and cognitive impairment. Corticosteroids prior to initiating effective therapy appear to have a detrimental effect, contributing to rapid progression of disease.

*Bibliography is available at Expert Consult.*
Bibliography
Entamoeba species infect or colonizes up to 10% of the world’s population, particularly in resource-limited settings. In most infected individuals, Entamoeba histolytica or a related species parasitizes the lumen of the gastrointestinal tract and causes few symptoms or sequelae. E. histolytica is the only invasive species and can cause amebic colitis with parasitic invasion of the intestinal mucosa and amebic liver abscess with dissemination of the parasite to the liver.

ETIOLOGY
Three morphologically identical but genetically distinct species of Entamoeba commonly infect humans. Entamoeba dispar, the most prevalent species, does not cause symptomatic disease. Entamoeba moshkovskii, previously thought to be nonpathogenic, has been shown to cause diarrhea in infants. E. histolytica, the main pathogenic species, causes a spectrum of disease and can become invasive in 4-10% of infected patients. Patients previously described as asymptomatic carriers of E. histolytica based on microscopy findings were likely harboring E. dispar. Four other species of nonpathogenic Entamoeba are known to colonize the human gastrointestinal tract: E. coli, E. hartmanni, E. gingivalis, and E. polecki.

Infection is acquired through the ingestion of parasite cysts, which measure 10-18 µm in diameter and contain 4 nuclei. Cysts are resistant to harsh environmental conditions, including chlorine concentrations commonly used in water purification, but can be killed by heating to 55°C (131°F). After ingestion, cysts are resistant to gastric acidity and digestive enzymes and germinate in the small intestine to form trophozoites. These large, actively motile organisms colonize the lumen of the large intestine and may invade the mucosal lining. Infection is not
usually transmitted by trophozoites, as these rapidly degenerate outside the body and are unable to survive the low pH of the stomach if swallowed.

**EPIDEMIOLOGY**

Prevalence of infection with *E. histolytica* varies greatly depending on region and socioeconomic status. Most prevalence studies have not distinguished between *E. histolytica* and *E. dispar*, and thus the true prevalence of *E. histolytica* infection is not known. It is estimated that infection with *E. histolytica* leads to 50 million cases of symptomatic disease and 40,000-110,000 deaths annually. Amebiasis is the second leading parasitic cause of death worldwide, after malaria. Prospective studies show that 4-10% of individuals infected with *E. histolytica* develop amebic colitis and that <1% of infected individuals develop disseminated disease, including amebic liver abscess. These numbers vary by region; for example, in South Africa and Vietnam, liver abscesses form a disproportionately large number of the cases of invasive disease caused by *E. histolytica*. Amebic liver abscesses are rare in children and occur equally in male and female children; in adults, amebic liver abscesses occur predominantly in men.

Amebiasis is endemic to Africa, Latin America, India, and Southeast Asia. In the United States, amebiasis is seen most frequently in immigrants from and in travelers to developing countries. Residents of mental health institutions and men who have sex with men are also at increased risk for invasive amebiasis. Food or drink contaminated with *Entamoeba* cysts and oral-anogenital sex are the most common means of infection. Untreated water and night soil (human feces used as fertilizer) are important sources of infection. Food handlers shedding amebic cysts play a role in spreading infection. Direct contact with infected feces can also result in person-to-person transmission.

**PATHOGENESIS**

Trophozoites are responsible for tissue invasion and destruction. These attach to colonic epithelial cells by agalactose and N-acetyl-D-galactosamine–specific lectin. This lectin is also thought to be responsible for resistance to complement-mediated lysis. Once attached to the colonic mucosa, amebas release proteases that allow for penetration through the epithelial layer. Host cells are destroyed by cytosis and apoptosis. Cytolysis is mediated by trophozoite release of amebapores (pore-forming proteins), phospholipases, and hemolysins. Amebapores, which cause a massive influx of extracellular calcium, may also be partially responsible for the induction of apoptosis that occurs with amebic liver disease and colitis. Once host cells are partially digested by amebic proteases, the degraded material is internalized through phagocyosis. Early invasive amebiasis produces significant inflammation, due in part to parasite-mediated activation of nuclear factor-κB. Once *E. histolytica* trophozoites invade the intestinal mucosa, the organisms multiply and spread laterally underneath the intestinal epithelium to produce the characteristic flask-shaped ulcers. Amebas produce similar lytic lesions if they reach the liver. These lesions are commonly called abscesses, although they contain no granulocytes. Well-established ulcers and amebic liver abscesses demonstrate little local inflammatory response.

Immunity to infection is associated with a mucosal secretory IgA response against the galactose/N-acetyl-D-galactosamine lectin. Neutrophils appear to be important in initial host defense, but *E. histolytica*–induced epithelial cell damage releases neutrophil chemoattractants, and *E. histolytica* is able to kill neutrophils, which then release mediators that further damage epithelial cells. The disparity between the extent of tissue destruction by amebas and the absence of a local host inflammatory response in the presence of systemic humoral (antibody) and cell-mediated responses may reflect both parasite-mediated apoptosis and the ability of the trophozoite to kill not only epithelial cells but neutrophils, monocytes, and macrophages. Studies show a protective role of the hormone leptin in mucosal resistance. A malnourished state, in which leptin levels are low, and a genetic polymorphism in the leptin receptor can increase susceptibility to invasive disease.

The sequencing of the *E. histolytica* genome has led to further insights into the pathogenesis of *E. histolytica* disease. The genome is functionally tetraploid and contains evidence of lateral gene transfer from bacteria. It has been demonstrated that the amebapore-A (Ap-A) gene, along with other important genes, can be epigenetically silenced using plasmids with specifically engineered sequences or short hairpin RNAs. Transcriptional profiling using proteomics and microarrays has likewise identified several candidate virulence factors. Several classes of proteases that may be associated with pathogenesis have been identified, including the cysteine proteases binding family proteins (CPBF8), which modulate lysosome and phagosome function, and M8 metalloc protease EhMSP-1, which likely has a key role in amebic invasion and is notably absent in *E. dispar*.

**CLINICAL MANIFESTATIONS**

Clinical presentations range from asymptomatic cyst passage to amebic colitis, amebic dysentery, ameboma, and extraintestinal disease. Up to 10% of infected persons develop invasive disease within a year. Thus, asymptomatic carriers should be treated. Severe disease is more common in young children, pregnant women, malnourished individuals, and persons taking corticosteroids, and invasive disease is more common in men. Extraintestinal disease usually involves the liver, but less common extraintestinal manifestations include amebic brain abscess, pleuropulmonary disease, ulcerative skin, and genitourinary lesions.

**Amebic Colitis**

Amebic colitis may occur within 2 wk of infection or may be delayed for months. The onset is usually gradual, with colicky abdominal pains and frequent bowel movements (6-8/day). Diarrhea is frequently associated with tenesmus. Almost all stool is heme-positive, but most patients do not present with grossly bloody stools. Generalized constitutional symptoms and signs are characteristically absent, with fever documented in only one third of patients. Amebic colitis affects all age groups but is strikingly common in children 1-5 yr of age. Severe amebic colitis in infants and young children tends to be rapidly progressive with more frequent extraintestinal involvement and high mortality rates, particularly in tropical countries. Amebic dysentery can result in dehydration and electrolyte disturbances.

**Amebic Liver Abscess**

Amebic liver abscess, a serious manifestation of disseminated infection, is uncommon in children. Although diffuse liver enlargement has been associated with intestinal amebiasis, liver abscesses occur in <1% of infected individuals and may appear in patients with no clear history of intestinal disease. Amebic liver abscess may occur months to years after exposure, so obtaining a careful travel history is critical. In children, fever is the hallmark of amebic liver abscess and is frequently associated with abdominal pain, abdominal distention, and enlargement and tenderness of the liver. Changes at the base of the right lung, such as elevation of the diaphragm and atelectasis or effusion, may also occur.

**Men Who Have Sex with Men and HIV Coinfection**

Epidemiologic studies from both developed and developing countries have shown an increased risk for *E. histolytica* infection among men who have sex with men. This risk is further increased in HIV because of increased host susceptibility, and is particularly pronounced in men who have sex with men with HIV infection.

**LABORATORY FINDINGS**

Laboratory examination findings are often unremarkable in uncomplicated amebic colitis. Laboratory findings in amebic liver abscess are a slight leukocytosis, moderate anemia, high erythrocyte sedimentation rate, and elevations of hepatic enzyme (particularly alkaline phosphatase) levels. Stool examination for amebas is negative in more than half of patients with documented amebic liver abscess. Ultrasonography, CT, or MRI can localize and delineate the size of the abscess cavity (Fig. 281-1). The most common finding is a single abscess in the right hepatic lobe in about one half of these cases. Higher-resolution
ultrasound and CT studies show that left lobe abscess and multiple abscesses occur more often than previously recognized.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

A diagnosis of amebic colitis is made in the presence of compatible symptoms with detection of *E. histolytica* antigens in stool. This approach has a >95% sensitivity and specificity and coupled with a positive serology test is the most accurate means of diagnosis in developed countries. The *E. histolytica* II stool antigen detection test (TechLab, Blacksburg, VA) is able to distinguish *E. histolytica* from *E. dispar* infection. Microscopic examination of stool samples has a sensitivity of 60%. Sensitivity can be increased to 85-95% by examining 3 stools, as excretion of cysts can be intermittent. However, microscopy cannot differentiate between *E. histolytica* and *E. dispar* unless phagocytosed erythrocytes (specific for *E. histolytica*) are seen. In highly endemic areas, trophozoites without phagocytosed erythrocytes may reflect co-infection with *E. dispar* in a patient with another cause of colitis, such as shigellosis. Endoscopy and biopsies of suspicious areas should be performed when stool sample results are negative and suspicion for amebiasis remains high.

Various serum antiamebic antibody tests are available. Serologic results are positive in 70-80% of patients with invasive disease (colitis or liver abscess) at presentation and in >90% of patients after 7 days of disease symptoms. The most sensitive serologic test, indirect hemagglutination, yields a positive result even years after invasive infection. Therefore, many uninfected adults and children in highly endemic areas demonstrate antibodies to *E. histolytica*. Polymerase chain reaction detection in stool of *E. histolytica* is also able to distinguish *E. histolytica* from *E. dispar* but is less sensitive (72%) than the stool antigen test. Rapid antigen and antibody tests for bedside diagnosis in the developing world have been developed and are currently being tested. A high-throughput Luminex technique for simultaneous detection and differentiation of Entamoeba species has also been developed. In addition, a loop-mediated isothermal amplification assay that can be optimized for field use is under development.

The **differential diagnosis** for amebic colitis includes colitis caused by bacterial (*Shigella, Salmonella*, enteropathogenic *Escherichia coli*, *Campylobacter, Yersinia, Clostridium difficile*), mycobacterial (tuberculosis and atypical mycobacteria), and viral (cytomegalovirus) pathogens, as well as noninfectious causes such as inflammatory bowel disease. Pyogenic liver abscess from bacterial infection, hepatoma, and echinococcal cysts are in the differential diagnosis for amebic liver abscess. However, echinococcal cysts are rarely associated with systemic symptoms such as fever unless there is cyst rupture or leakage.

**COMPLICATIONS**

Complications of amebic colitis include acute necrotizing colitis, ameboma, toxic megacolon, extraintestinal extension, or local perforation and peritonitis. Less commonly, a chronic form of amebic colitis develops, often recurring over several years. Amebomas are nodular foci of proliferative inflammation that sometimes develop in the wall of the colon. Chronic amebiasis should be excluded before initiating corticosteroid treatment for inflammatory bowel disease, as corticosteroid therapy given during active amebic colitis is associated with high mortality rates.

An amebic liver abscess may rupture into the peritoneum, pleural cavity, skin, and pericardium. Cases of amebic abscesses in extrahepatic sites, including the lung and brain, have been reported.

**TREATMENT**

Invasive amebiasis is treated with a nitroimidazole such as metronidazole or tinidazole and then a luminal amebicide (Table 281-1).

†Not available in the United States.
Tinidazole has similar efficacy to metronidazole with shorter and simpler dosing and less-frequent adverse effects. These adverse effects include nausea, abdominal discomfort, and a metallic taste that disappears after completion of therapy. Therapy with a nitroimidazole should be followed by treatment with a luminal agent, such as paromomycin (which is preferred) or iodoquinol. Diloxanide furoate can also be used in children older than 2 yr of age, but it is no longer available in the United States. Paromomycin should not be given concurrently with metronidazole or tinidazole, because diarrhea is a common side effect of paromomycin and may confuse the clinical picture. Asymptomatic intestinal infection with *E. histolytica* should be treated preferably with paromomycin or alternatively with either iodoquinol or diloxanide furoate. For fulminant cases of amebic colitis, some experts suggest adding dehydroemetine (1 mg/kg/day subcutaneously or IM, never IV), available only through the Centers for Disease Control and Prevention. Patients should be hospitalized for monitoring if dehydroemetine is administered. Dehydroemetine should be discontinued if tachycardia, T-wave depression, arrhythmia, or proteinuria develops.

Broad-spectrum antibiotic therapy may be indicated in fulminant colitis to cover possible spillage of intestinal bacteria into the peritoneum and translocation into the bloodstream. Intestinal perforation and toxic megacolon are indications for surgery. In amebic liver abscess, image-guided aspiration of large lesions or left lobe abscesses may be necessary if rupture is imminent or if the patient shows a poor clinical response 4–6 days after administration of amebicidal drugs. A Cochrane metaanalysis comparing metronidazole and metronidazole plus aspiration in uncomplicated amebic liver abscess showed that there is insufficient evidence to make any recommendation for or against this approach. Chloroquine, which concentrates in the liver, may also be a useful adjunct to nitroimidazoles in the treatment of amebic liver abscess. To confirm cure, stool examination should be repeated every 2 wk following completion of therapy until clear.

**PROGNOSIS**

Most infections evolve to either an asymptomatic carrier state or eradication. Extraintestinal infection carries about a 5% mortality rate.

**PREVENTION**

Control of amebiasis can be achieved by exercising proper sanitation and avoiding fecal-oral transmission. Regular examination of food handlers and thorough investigation of diarrheal episodes may help identify the source of infection. No prophylactic drug or vaccine is currently available for amebiasis. Immunization with a combination of galactose/N-acetyl-d-galactosamine lectin and CpG oligodeoxynucleotides is protective against amebic trophozoite challenge in animals, and an intranasal galactose-lectin subunit vaccine is protective in baboons.

Giardiasis and Balantidiasis

282.1 *Giardia lamblia*
Chandy C. John

*Giardia lamblia* is a flagellated protozoan that infects the duodenum and small intestine. Infection results in clinical manifestations that range from asymptomatic colonization to acute or chronic diarrhea and malabsorption. Infection is more prevalent in children than in adults. *Giardia* is endemic in areas of the world with poor levels of sanitation. It is also an important cause of morbidity in developed countries, where it is associated with urban childcare centers, residential institutions for the developmentally delayed, and waterborne and foodborne outbreaks. *Giardia* is a particularly significant pathogen in people with malnutrition, certain immunodeficiencies, and cystic fibrosis.

**ETIOLOGY**

The life cycle of *G. lamblia* (also known as *Giardia intestinalis* or *Giardia duodenalis*) is composed of 2 stages: trophozoites and cysts. *Giardia* infects humans after ingestion of as few as 10-100 cysts (which measure 8-10 µm in diameter). Each ingested cyst produces 2 trophozoites in the duodenum. After excystation, trophozoites colonize the lumen of the duodenum and proximal jejunum, where they attach to the brush border of the intestinal epithelial cells and multiply by binary fission. The body of the trophozoite is teardrop shaped, measuring 10-20 µm in length and 5-15 µm in width. *Giardia* trophozoites contain 2 oval nuclei anteriorly, a large ventral disk, a curved median body posteriorly, and 4 pairs of flagella. As detached trophozoites pass down the intestinal tract, they encyst to form oval cysts that contain 4 nuclei. Cysts are passed in stools of infected individuals and may remain viable in water for as long as 2 mo. Their viability often is not affected by the usual concentrations of chlorine used to purify water for drinking.

*Giardia* strains that infect humans are diverse biologically, as shown by differences in antigens, restriction endonuclease patterns, DNA fingerprinting, isoenzyme patterns, and pulsed-field gel electrophoresis. Studies suggest that different *Giardia* genotypes may cause unique clinical manifestations, but these findings appear to vary according to the geographic region tested.

**EPIDEMIOLOGY**

*Giardia* occurs worldwide and is the most common intestinal parasite identified in public health laboratories in the United States, where it is estimated that up to 2 million cases of giardiasis occur annually. *Giardia* infection usually occurs sporadically, but *Giardia* is a frequently identified etiologic agent of outbreaks associated with drinking water. The age-specific prevalence of giardiasis is high during childhood and begins to decline after adolescence. The asymptomatic carrier rate of *G. lamblia* in the United States is as high as 20-30% in children younger than 36 mo of age attending childcare centers. Asymptomatic carriage may persist for several months.

Transmission of *Giardia* is common in certain high-risk groups, including children and employees in childcare centers, consumers of contaminated water, travelers to certain areas of the world, men who have sex with men, and persons exposed to certain animals. The major reservoir and vehicle for spread of *Giardia* appears to be water contaminated with *Giardia* cysts, but foodborne transmission occurs. The seasonal peak in age-specific case reports coincides with the summer recreational water season and might be a result of the extensive use of communal swimming venues by young children, the low infectious dose, and the extended periods of cyst shedding that can occur. In addition, *Giardia* cysts are relatively resistant to chlorination and to ultraviolet light irradiation. Boiling is effective for inactivating cysts.

Person-to-person spread also occurs, particularly in areas of low hygiene standards, frequent fecal-oral contact, and crowding. Individual susceptibility, lack of toilet training, crowding, and fecal contamination of the environment all predispose to transmission of enteropathogens, including *Giardia*, in childcare centers. Childcare centers play an important role in transmission of urban giardiasis, with secondary attack rates in families as high as 17-30%. Children in childcare centers may pass cysts for several months. Campers who drink untreated stream or river water, particularly in the western United States, and residents of institutions for the developmentally delayed are also at increased risk for infection.

Humoral immunodeficiencies, including common variable hypogammaglobulinemia and X-linked agammaglobulinemia, predispose
Giardiasis

areas. correlate with a decrease in cognitive function in children in endemic been associated with growth stunting, and repeated absorption may occur. Abnormal stool patterns may alternate with contain blood, mucus, or fecal leukocytes. Varying degrees of malab-
crinoids, bloating, malaise, flatulence, nausea, anorexia, and weight loss

ally trophozoites may migrate into bile or pancreatic ducts. The organism, acute infectious diarrhea, or chronic diarrhea with per-
thrive and abdominal pain or cramping. Children who

infections occur more frequently in children than in adults. Most symptomatic patients usually have a limited period of acute diarrheal disease with or without low-grade fever, nausea, and anorexia; in a small proportion of patients, an intermittent or more protracted course characterized by diarrhea, abdominal distention and cramps, bloating, malaise, flatulence, nausea, anorexia, and weight loss develops (Table 282-1). Stools initially may be profuse and watery and later become greasy and foul smelling and may float. Stools do not contain blood, mucus, or fecal leukocytes. Varying degrees of malab-
sorbed by EIA, whereas others giardiasis are the tests of choice for giardiasis in most

in the duodenum. Human milk contains glycoconjugates and secretory

immunoglobulin A deficiency is also associated with

humoral immunity in controlling giardiasis. Selective

immunoglobulin A deficiency is also associated with Giardia infection. Although many individuals with AIDS have relatively mild Giardia
infections, some reports suggest that severe Giardia infection, often refractory to treatment, may occur in a subset of individuals with AIDS. There is a higher incidence of Giardia infection in patients with cystic fibrosis, probably owing to local factors such as the increased amount of mucus, which may protect the organism against host factors in the duodenum. Human milk contains glycoconjugates and secretory

immunoglobulin A antibodies that may provide protection to nursing infants against Giardia.

**CLINICAL MANIFESTATIONS**

The incubation period of Giardia infection usually is 1-2 wk but may be longer. A broad spectrum of clinical manifestations occurs, depend-
ing on the interaction between G. lamblia and the host. Children who are exposed to G. lamblia may experience asymptomatic excretion of the organism, acute infectious diarrhea, or chronic diarrhea with per-

Giardia was the cause of 15% of nongiardiasis diarrhea illnesses in children examined in U.S. out-
patient clinics in 1 study. Most infections in both children and adults are asymptomatic. There usually is no extraintestinal spread, but occasion-
ally trophozoites may migrate into bile or pancreatic ducts.

Symptomatic infections occur more frequently in children than in adults. Most symptomatic patients usually have a limited period of acute diarrheal disease with or without low-grade fever, nausea, and anorexia; in a small proportion of patients, an intermittent or more protracted course characterized by diarrhea, abdominal distention and cramps, bloating, malaise, flatulence, nausea, anorexia, and weight loss develops (Table 282-1). Stools initially may be profuse and watery and later become greasy and foul smelling and may float. Stools do not contain blood, mucus, or fecal leukocytes. Varying degrees of malab-
sorbed by EIA, whereas others giardiasis are the tests of choice for giardiasis in most

in the duodenum. Human milk contains glycoconjugates and secretory

immunoglobulin A deficiency is also associated with

humoral immunity in controlling giardiasis. Selective

immunoglobulin A deficiency is also associated with Giardia infection. Although many individuals with AIDS have relatively mild Giardia
infections, some reports suggest that severe Giardia infection, often refractory to treatment, may occur in a subset of individuals with AIDS. There is a higher incidence of Giardia infection in patients with cystic fibrosis, probably owing to local factors such as the increased amount of mucus, which may protect the organism against host factors in the duodenum. Human milk contains glycoconjugates and secretory

immunoglobulin A antibodies that may provide protection to nursing infants against Giardia.

**Diagnosis**

Giardiasis should be considered in children who have acute non-
dysenteric diarrhea, persistent diarrhea, intermittent diarrhea and constipation, malabsorption, chronic crampy abdominal pain and bloating, failure to thrive, or weight loss. It should be particularly high in the differential diagnosis of children in child care, children in contact with an index case, children with a history of recent travel to an endemic area, and children with humoral immunodeficiencies.

Testing for giardiasis should be standard for internationally adopted children from Giardia-endemic areas, and screening for iron defi-
cency should be considered in internationally adopted children with giardiasis.

Stool enzyme immunoassay (EIA) or direct fluorescent antibody tests for Giardia antigens are the tests of choice for giardiasis in most situations. EIA is less reporter dependent and more sensitive for detec-
tion of Giardia than microscopy. Some studies report that a single stool is sufficiently sensitive for detection of Giardia by EIA, whereas others suggest that sensitivity is increased with testing of 2 samples. A diag-
nosis of giardiasis was traditionally established by microscopy docu-

mentation of trophozoites or cysts in stool specimens, but 3 stool specimens are required to achieve a sensitivity of >90% using this approach. In patients in whom other parasitic intestinal infections are in the differential diagnosis, microscopy examination of stool allows evaluation for these infections in addition to Giardia. Laboratories can reduce reagent and personnel costs by pooling specimens submitted for detection of Giardia before evaluation by microscopy or EIA. Poly-

merase chain reaction and gene probe–based detection systems spe-
cific for Giardia have been used in environmental monitoring but at present remain research tools. Multiplex polymerase chain reaction testing for multiple parasitic pathogens may become a viable option for testing in the future.

In patients with chronic symptoms in whom giardiasis is suspected but in whom testing of stool specimens for Giardia yields a negative result, aspiration or biopsy of the duodenum or upper jejunum should be considered. In a fresh specimen, trophozoites usually can be visualized by direct wet mount. An alternate method of directly obtaining duodenal fluid is the commercially available Entero-Test (Hedeco Corp, Mountain View, CA), but this method is less sensitive than aspiration or biopsy. The biopsy can be used to make touch prepara-
tions and tissue sections for identification of Giardia and other enteric pathogens and also to visualize changes in histology. Biopsy of the small intestine should be considered in patients with characteristic clinical symptoms, negative stool and duodenal fluid specimen find-
ings, and 1 or more of the following: abnormal radiographic findings (such as edema and segmentation in the small intestine); abnormal lactose tolerance test result; absent secretory immunoglobulin A level; hypogammaglobulinemia; and achlorhydria. Duodenal biopsy may show findings consistent with chronic inflammation, including eosino-

phlic infiltration of the lamina propria.

Radiographic contrast studies of the small intestine may show non-
specific findings such as irregular thickening of the mucosal folds. Blood cell counts usually are normal. Giardiasis is not tissue invasive and is not associated with peripheral blood eosinophilia.

**Treatment**

Children with acute diarrhea in whom Giardia organisms are identi-
fied should receive therapy. In addition, children who manifest failure to thrive or exhibit malabsorption or gastrointestinal tract symptoms such as chronic diarrhea should be treated.

Asymptomatic excretors generally are not treated except in specific instances such as outbreak control, prevention of household trans-
mission by toddlers to pregnant women and patients with hypo-
gammaglobulinemia or cystic fibrosis, and situations requiring oral antibiotic treatment where Giardia may produce malabsorption of the antibiotic.

The FDA has approved tinidazole and nitazoxanide for the treat-
ment of Giardia in the United States. Both medications have been used to treat Giardia in thousands of patients in other countries and have excellent safety and efficacy against Giardia (Table 282-2). Tinidazole

has the advantage of single-dose treatment and very high efficacy (>90%), while nitazoxanide has the advantage of a suspension form, high efficacy (80-90%), and very few adverse effects. Metronidazole, though never approved by the FDA for treatment of Giardia, is also highly effective (80-90% cure rate), and the generic form is considerably less expensive than tinidazole or nitazoxanide. Frequent adverse effects are seen with metronidazole therapy, and it requires 3 times a day dosing for 5-7 days. Suspension forms of tinidazole and metronidazole must be compounded by a pharmacy; neither drug is sold in suspension form.

**Second-line alternatives** for the treatment of patients with giardiasis include albendazole, paromomycin, and quinacrine (see Table 282-2). Albendazole may be of similar efficacy to metronidazole. Albendazole has few adverse effects and is effective against many helminths, making it useful for treatment when multiple intestinal parasites are identified or suspected. Paromomycin is a nonabsorbable aminoglycoside and is less effective than other agents but is recommended for treatment of pregnant women with giardiasis because of potential teratogenic effects of other agents. Quinacrine is effective and inexpensive but is not available commercially and must be obtained from compounding pharmacies (see Table 282-2). Quinacrine can also rarely have serious side effects, including hallucinations and psychosis. Refractory cases of giardiasis have been successfully treated with nitazoxanide, prolonged courses of tinidazole, or a 3 wk course of metronidazole and quinacrine.

**PROGNOSIS**

Symptoms recur in some patients in whom reinfection cannot be documented and in whom an immune deficiency such as an immunoglobulin abnormality is not present, despite use of appropriate therapy. Several studies have demonstrated that variability in antimicrobial susceptibility exists among strains of *Giardia*, and in some instances resistant strains have been demonstrated. Combined therapy may be useful for infection that persists after single-drug therapy, assuming reinfection has not occurred and the medication was taken as prescribed.

**PREVENTION**

Infected persons and persons at risk should practice strict handwashing after any contact with feces. This point is especially important for caregivers of diapered infants in childcare centers, where diarrhea is common and *Giardia* organism carriage rates are high.

Methods to purify public water supplies adequately include chlorination, sedimentation, and filtration. Inactivation of *Giardia* cysts by chlorine requires the coordination of multiple variables such as chlorine concentration, water pH, turbidity, temperature, and contact time. These variables cannot be appropriately controlled in all municipalities and are difficult to control in swimming pools. Individuals, especially children in diapers, should avoid swimming if they have diarrhea. Individuals should also avoid swallowing recreational water and drinking untreated water from shallow wells, lakes, springs, ponds, streams, and rivers.

Travelers to endemic areas are advised to avoid uncooked foods that might have been grown, washed, or prepared with water that was potentially contaminated. Purification of drinking water can be achieved by a filter with a pore size of <1 µm or that has been National Sanitation Foundation rated for cyst removal, or by brisk boiling of water for at least 1 min. Treatment of water with chlorine or iodine is less effective but may be used as an alternate method when boiling or filtration is not possible.

Bibliography is available at Expert Consult.

### 282.2 Balantidiasis

**Chandy C. John**

*Balantidium coli* is a ciliated protozoan and is the largest protozoan that parasitizes humans. Both trophozoites and cysts may be identified in feces. Disease caused by this organism is uncommon in the United States and generally is reported where there is a close association of humans with pigs, which are the natural hosts of *B. coli*. Because the organism infects the large intestine, symptoms are consistent with large bowel disease, similar to those associated with amebiasis and trichuriasis, and include nausea, vomiting, lower abdominal pain, tenesmus, and bloody diarrhea. Symptoms associated with chronic infection include abdominal cramps, watery diarrhea with mucus, occasionally bloody diarrhea, and colonic ulcers similar to those associated with *Entamoeba histolytica*. Extraintestinal spread of *B. coli* is rare and usually occurs only in immunocompromised patients. Most infections are asymptomatic.

Diagnosis using direct saline mounts is established by identification of trophozoites (50-100 µm long) or spherical or oval cysts (50-70 µm in diameter) in stool specimens. Trophozoites usually are more numerous than cysts. The recommended treatment regimen is metronidazole (45 mg/kg/day divided tid PO; maximum: 750 mg/dose) for 5 days, or tetracycline (40 mg/kg/day divided qid PO; maximum: 500 mg/dose) for 10 days for persons older than 8 yr of age. An alternative is iodoquinol (40 mg/kg/day divided tid PO; maximum: 650 mg/dose) for 20 days. Prevention of contamination of the environment by pig feces is the most important means for control.

Bibliography

Chapter 283  Cryptosporidium, Isospora, Cyclospora, and Microsporidia
Patricia M. Flynn

Cryptosporidium, Isospora, Cyclospora, and Microsporidia

The spore-forming intestinal protozoa Cryptosporidium, Isospora, and Cyclospora are important intestinal pathogens in both immunocompetent and immunocompromised hosts. Cryptosporidium, Isospora, and Cyclospora are coccidian parasites that predominantly infect the epithelial cells lining the digestive tract. Microsporidia were formerly considered spore-forming protozoa but have been reclassified as fungi. Microsporidia are ubiquitous, obligate intracellular parasites that infect many other organ systems in addition to the gastrointestinal tract and cause a broader spectrum of disease.

CRYPTOSPORIDIUM
Cryptosporidium is recognized as a leading protozoal cause of diarrhea in children worldwide and is a common cause of outbreaks in childcare centers; it is also a significant pathogen in immunocompromised patients.

Etiology
Cryptosporidium hominis and Cryptosporidium parvum cause most cases of cryptosporidiosis in humans. Disease is initiated by ingestion of infectious oocysts that release 4 sporozoites that invade enterocytes, primarily in the small intestine. The cysts are immediately infectious to other hosts or can reinfect the same host.

Epidemiology
Cryptosporidiosis is associated with diarrheal illness worldwide and is more prevalent in developing countries and among children younger than 2 yr of age. It has been implicated as an etiologic agent of persistent diarrhea in the developing world and as a cause of significant morbidity and mortality from malnutrition, including permanent effects on growth.

Transmission of Cryptosporidium to humans can occur by close association with infected animals, via person-to-person transmission, or from environmentally contaminated water. Although zoonotic transmission, especially from cows, occurs in persons in close association with animals, person-to-person transmission is probably responsible for cryptosporidiosis outbreaks within hospitals and childcare centers where transmission rates as high as 67% have been reported. Recommendations to prevent outbreaks in childcare centers include strict handwashing, use of protective clothes or diapers capable of retaining liquid diarrhea, and separation of diapering and food-handling areas and responsibilities.

Outbreaks of cryptosporidial infection are associated with contaminated community water supplies and recreational waters, including lakes and chlorinated swimming pools. Wastewater in the form of raw sewage and runoff from dairies and grazing lands can contaminate both drinking and recreational water sources. It is estimated that Cryptosporidium oocysts are present in 65-97% of the surface water in the United States. The organism’s small size (4-6 μm in diameter), resistance to chlorination, and ability to survive for long periods outside a host creates problems in public water supplies.

Clinical Manifestations
The incubation period is 2-14 days. Infection with Cryptosporidium is associated with profuse, watery, nonbloody diarrhea that can be accompanied by diffuse crampy abdominal pain, nausea, vomiting, and anorexia. Although less common in adults, vomiting occurs in more than 80% of children with cryptosporidiosis. Nonspecific symptoms such as myalgia, weakness, and headache also may occur. Fever occurs in 30-50% of cases. Malabsorption, lactose intolerance, dehydration, weight loss, and malnutrition often occur in severe cases. Recently, the clinical spectrum and disease severity has been linked with both the infecting species and host human leukocyte antigen class I and class II alleles.

In immunocompetent persons, the disease is usually self-limiting, typically 5-10 days, although diarrhea may persist for several weeks and oocyst shedding may persist many weeks after symptoms resolve. Chronic diarrhea is common in individuals with immunodeficiency, such as congenital hypogammaglobulinemia or HIV infection. Symptoms and oocyst shedding can continue indefinitely and may lead to severe malnutrition, wasting, anorexia, and even death.

Cryptosporidiosis in immunocompromised hosts is often associated with biliary tract disease, characterized by fever, right upper quadrantal pain, nausea, vomiting, and diarrhea. It also is associated with pancreatitis. Respiratory tract disease, with symptoms of cough, shortness of breath, wheezing, croup, and hoarseness, is very rare.

Diagnosis
Infection can be diagnosed by microscopy using modified acid-fast stain or polymerase chain reaction, but immunodetection of antigens on the surface of the organism in stool samples using monoclonal antibody–based assays is the current diagnostic method of choice. In stool, oocysts appear as small, spherical bodies (2-6 μm) and stain red with modified acid-fast staining. Because Cryptosporidium does not invade below the epithelial layer of the mucosa, fecal leukocytes are not found in stool specimens. Oocyst shedding in feces can be intermittent, and several fecal specimens (at least 3 for an immunocompetent host) should be collected for microscopic examination. Serologic diagnosis is not helpful in acute cryptosporidiosis.

In tissue sections, Cryptosporidium organisms can be found along the microvillus region of the epithelia that line the gastrointestinal tract. The highest concentration usually is detected in the jejunal. Histologic section results reveal villus atrophy and blunting, epithelial flattening, and inflammation of the lamina propria.

Treatment
Often the diarrheal illness attributable to cryptosporidiosis is self-limited in immunocompetent patients and requires no specific antimicrobial therapy. Treatment should focus on supportive care, including rehydration orally or, if fluid losses are severe, intravenously. Nitazoxanide (100 mg bid PO for 3 days for children 1-3 yr of age; 200 mg bid PO for children 4-11 yr of age; 500 mg bid PO for children ≥12 yr of age) is approved for treatment of diarrhea caused by Cryptosporidium. Clinical studies have not definitively demonstrated that nitazoxanide is superior to placebo in trials of HIV-infected (with low CD4 counts) or immunocompromised patients. However, given the severity of the infection in these populations, nitazoxanide treatment is usually initiated. In patients with HIV infection, treatment with combination antiretroviral therapy should also be administered to improve immune function. Other agents that have been suggested for treatment in clinical reports or small studies include orally administered human serum immunoglobulin or bovine colostrum, paromomycin, spiramycin, azithromycin, and roxithromycin or a combination of antibiotics.

ISOSPORA
Like Cryptosporidium, Isospora belli (also called Cystoisospora) is implicated as a cause of diarrhea in institutional outbreaks and in travelers and has also been linked with contaminated water and food. Isospora appears to be more common in tropical and subtropical climates and in developing areas, including South America, Africa, and Southeast Asia. Isospora has not been associated with animal contact. It is also an infrequent cause of diarrhea in patients with AIDS in the United States but may infect up to 15% of AIDS patients in Haiti.
The life cycle and pathogenesis of infection with Isospora species are similar to those of Cryptosporidium organisms except that oocysts excreted in the stool are not immediately infectious and must undergo further maturation at temperatures below 37°C (98.6°F). Thus, direct person-to-person transmission is unlikely. The most common clinical manifestation is watery, nonbloody diarrhea. Symptoms of infection are indistinguishable from those of cryptosporidiosis, although fever may be a more common finding. Eosinophilia may be present in up to 50% of cases, contrasting with other enteric protozoan infections. The diagnosis is established by detecting the oval, 22-33 µm long by 10-19 µm wide, oocysts by using modified acid-fast staining of the stool. Each oocyst contains 2 sporocysts with 4 sporozoites in each. Fecal leukocytes are not detected. Oocysts are shed in low number, underscoring the need for repeated stool examinations. Presence of oocysts in the gastrointestinal tract is almost always associated with clinical symptoms. Histologic appearance of gastrointestinal epithelium reveals blunting and atrophy of the villi, acute and chronic inflammation, and crypt hyperplasia.

Isosporiasis responds promptly to treatment with oral trimethoprim-sulfamethoxazole (TMP-SMZ) (5 mg TMP and 25 mg SMZ/kg/dose; maximum: 160 mg TMP and 800 mg SMZ/dose bid for 10 days). In patients with AIDS, relapses are common and often necessitate higher doses of trimethoprim-sulfamethoxazole and/or maintenance therapy. Combination antiretroviral therapy associated with immune recovery may also result in improved symptoms. Ciprofloxacin, nitazoxanide, or a regimen of pyrimethamine alone or with folinic acid is effective in patients intolerant of sulfonamide drugs.

**CYCLOSPORA**

_Cyclospora cayetanensis_ is a coccidian parasite similar to but larger than *Cryptosporidium*. The organism infects both immunocompromised and immunocompetent individuals and is more common in children younger than 18 mo of age. The pathogenesis and pathologic findings of cyclosporiasis are similar to those of isosporiasis. Asymptomatic carriage of the organism has been found, but travelers who harbor the organism almost always have diarrhea. Outbreaks of cyclosporiasis are linked with contaminated food and water. Implicated foods include raspberries, lettuce, snow peas, basil, and other fresh food items. After fecal excretion, the oocysts must sporulate outside the host to become infectious. This finding explains the lack of person-to-person transmission.

The clinical manifestations of cyclosporiasis are similar to those of cryptosporidiosis and isosporiasis and follow an incubation period of approximately 7 days. Moderate Cyclospora illness is characterized by a median of 6 stools/day with a median duration of 10 days (range: 3-25 days). The duration of diarrhea in immunocompetent persons is characteristically longer in cyclosporiasis than in the other intestinal protozoan illnesses. Associated symptoms frequently include anorexia; fatigue; abdominal bloating or gas; abdominal cramps or pain; nausea; muscle, joint, or body aches; low-grade fever; chills; headache; and weight loss. Vomiting may occur. Bloody stools are uncommon. Biliary disease has been reported. Intestinal pathology includes inflammation with villus blunting.

The diagnosis is established by identification of oocysts in the stool. Oocysts are wrinkled spheres, measure 8-10 µm in diameter, and resemble large Cryptosporidium organisms. Each oocyst contains 2 sporocysts, each with 2 sporozoites. The organisms can be seen by using modified acid-fast, auramine-phol, or modified trichrome staining, but stain less consistently than Cryptosporidium. They can also be detected with phensosafarin stain and by autofluorescence using strong green or intense blue under ultraviolet epifluorescence.

Multiple stool samples enhance identification of the pathogen. New molecular diagnostic testing, including real-time polymerase chain reaction, is currently under investigation. Fecal leukocytes are not present.

The treatment of choice for cyclosporiasis is TMP-SMZ (5 mg TMP and 25 mg SMZ/kg/dose bid PO for 7 days; maximum: 160 mg TMP and 800 mg SMZ/dose). Ciprofloxacin or nitazoxanide is effective in patients intolerant of sulfonamide drugs.

**MICROSPORIDIA**

Microsporidia are ubiquitous and infect most animal groups, including humans. They are classified as fungi and multiple species of the phylum Microsporidia have been linked with human disease in both immunocompetent and immunocompromised hosts. The species most commonly associated with gastrointestinal disease are Enterocytozoon bieneusi and Encephalitozoon intestinalis.

Although still not definitive, the source of human infections is likely zoonotic. Like Cryptosporidium, there is concern for waterborne transmission through occupational and recreational contact with contaminated water sources. There is also the potential for foodborne outbreaks; the organisms have been identified on vegetables as a consequence of contaminated irrigation water. Vector-borne transmission is hypothesized because 1 species, *Brachyloma algerae*, typically infects mosquitoes. Finally, transplacental transmission has been reported in animals but not in humans. Once infected, intracellular division produces new spores that can spread to nearby cells, disseminate to other host tissues, or be passed into the environment via feces. Spores also have been detected in urine and respiratory epithelium, suggesting that some body fluids may also be infectious. Once in the environment, microsporidial spores remain infectious for up to 4 mo.

Initially, microsporidial intestinal infection had been almost exclusively reported in patients with AIDS, but there is increasing evidence that immunocompetent individuals are also commonly infected. Microsporidia-associated diarrhea is intermittent, copious, watery, and nonbloody. Abdominal cramping and weight loss may be present; fever is unusual. Stromal keratitis and encephalitis may also be associated with microsporidia infections. Disseminated disease involving most organs, including liver, heart, kidney, bladder, biliary tract, lung, bone, skeletal muscle, and sinuses, has been reported.

Microsporidia stain with modified trichrome, hematoxylin-eosin, Giemsa, Gram, periodic acid–Schiff, and acid-fast stains, but are often overlooked because of their small size (1-5 µm) and the absence of associated inflammation in surrounding tissues. Electron microscopy remains the reference method of detection. Multiple research laboratories report success with polymerase chain reaction technology in detecting microsporidia, both in human and environmental samples.

There is no proven therapy for microsporidial intestinal infections. Albendazole (adult dose 400 mg bid PO for 3 wk) is usually effective against E. _intestinalis_ infection, but is ineffective against infection caused by some microsporidial species. Fumagillin (adult dose 20 mg tid PO for 2 wk) was effective in a small controlled study of adults with _E. bieneusi_ infection and topical therapy with this agent was also demonstrated to be effective in HIV-infected adults with keratoconjunctivitis. Supportive care with hydration, correction of electrolyte imbalances, and nutrition should be used in gastrointestinal infection when clinically indicated. Improvement in underlying HIV infection with combination antiretroviral therapy also improves microsporidial symptoms.

Chapter 283  Cryptosporidium, Isospora, Cyclospora, and Microsporidia

Bibliography
Trichomoniasis, caused by the protozoan parasite *Trichomonas vaginalis*, is the most common nonviral sexually transmitted disease worldwide. It primarily causes vulvovaginitis in women but has been implicated in pelvic inflammatory disease, adverse outcomes in pregnancy, chronic prostatitis, and an increased risk of transmission of HIV.

**EPIDEMIOLOGY**

More than 170 million new cases of trichomoniasis occur yearly, the majority in resource-limited settings. Prevalence and incidence rates are likely underestimated, as most men and up to 30% of women are asymptomatic. Diagnostic accuracy using wet mount microscopy, the mainstay of diagnosis, is less sensitive than previously assumed. While the disease is easily treated, sequelae of untreated infection remain a significant cause of morbidity as a result of high reinfection rates from untreated partners, underrecognition of asymptomatic cases, and insensitive diagnostics.

Trichomoniasis is the most common parasitic infection in the United States, with approximately 7.4 million cases occurring each year. A population-based study conducted in 2005 showed a prevalence of 2.8% in women and 1.7% in men, and an overall prevalence of 2.3%. The incidence of trichomoniasis is highest among females with multiple sexual partners and in groups with the highest rates of other sexually transmitted infections. *T. vaginalis* is recovered from more than 60% of female partners of infected men and 70% of male sexual partners of infected women. Vaginal trichomoniasis is rare until menarche. Its presence in a younger child should raise the possibility of sexual abuse.

Trichomoniasis may be transmitted to neonates during passage through an infected birth canal. Infection in this setting is usually self-limited, but rare cases of neonatal vaginitis and respiratory infection have been reported.

**PATHOGENESIS**

*T. vaginalis* is an anaerobic, flagellated protozoan parasite. Infected vaginal secretions contain 10^7 to 10^8 more protozoa/mL. *T. vaginalis* is pear shaped and exhibits characteristic twitching motility in wet mount (Fig. 284-1). Reproduction is by binary fission. It exists only as vegetative cells; cyst forms have not been described. *T. vaginalis* damages host cells and tissues by a number of mechanisms. Adhesion molecules allow attachment of *T. vaginalis* to host cells, and hydrolases, proteases, and cytotoxic molecules act to destroy or impair the integrity of host cells. An iron-upregulated cysteine proteinase legumain-1 (TvLEGU-1) has been characterized as a major factor in cytadherence. There is increasing evidence that *T. vaginalis* is associated with low levels of *Lactobacillus* spp. and high levels of *Mycoplasma* spp. in the vaginal microbiota. However, whether trichomoniasis alters the bacterial flora or whether altered bacterial flora predisposes to trichomoniasis is uncertain. Parasite-specific antibodies and lymphocyte priming occur in response to infection, but durable protective immunity does not occur.

**CLINICAL MANIFESTATIONS**

The incubation period in females is 5-28 days. Symptoms may begin or exacerbate with menses. Most infected women eventually develop symptoms, although up to one third remain asymptomatic. Common signs and symptoms include a copious malodorous gray, frothy vaginal discharge, vulvovaginal irritation, dysuria, and dyspareunia. Physical examination may reveal a frothy discharge with vaginal erythema and cervical hemorrhages (“strawberry cervix”). The discharge usually has a pH of >4.5. Abdominal discomfort is unusual and should prompt evaluation for pelvic inflammatory disease (see Chapter 120).

Most infections in males are asymptomatic. Symptomatic males usually have dysuria and scant urethral discharge. Trichomonads occasionally cause epididymitis, prostatic involvement, and superficial penile ulceration. Infection is often self-limited, spontaneously resolving in 36% of men. *Trichomonas* has been implicated as a cause of recurrent or relapsing urethritis and can be isolated in 3-20% of men with *nongonococcal urethritis*. Treatment failures with standard therapy for gonorrhea and *Chlamydia* are frequently treated with anti-trichomonal therapy.

**DIAGNOSIS**

Trichomonads may be recognized in vaginal secretions by using the wet mount technique. This technique has been estimated to have a sensitivity of 60-70%; studies using more sensitive assays with nucleic acid probes and polymerase chain reaction suggest that this is closer to 35-60%. Although *Trichomonas* is sometimes seen on Papanicolaou smears and in urine, these methods are not considered reliable tests for disease. Wet mount examination of material obtained by platinum loop from the anterior urethra may reveal the organism in 50-90% of infected men. Microscopic examination of urine sediment after prostatic massage is also useful in infected men. Culture of the organism is the gold standard for detection, and commercial culture media are available. Enzyme-linked immunosorbent assay and direct fluorescent antigen testing of vaginal secretions are more sensitive than wet mount testing but less sensitive than culture for detection of *T. vaginalis* infection. In women, DNA immunoblot and polymerase chain reaction testing of vaginal secretions have similar sensitivity and specificity to culture. In men, these methods appear to be more sensitive at detection of infection than culture. Nucleic acid amplification testing and immunologic diagnostic kits for diagnosis of *Trichomonas* alone and in combination with other gynecologic diseases, such as *Candida* and *Gardinerella*, have been evaluated by multiple studies and have been found to be accurate and easy to use. The APTIMA TV (Gen-Probe Incorporated, CA) assay is an FDA-approved commercial nucleic acid amplification test that is highly sensitive and specific, particularly in asymptomatic patients. Two point-of-care kits for rapid testing, Affirm VP III (BD Diagnostic Systems, Sparks, MD) and OSOM *Trichomonas* Rapid Test (Genzyme Diagnostics, Cambridge, MA), have received approval by the FDA but are less sensitive than the APTIMA TV. Patients with *T. vaginalis* should be screened for other sexually transmitted infections, including *Chlamydia* and gonorrhea.
COMPLICATIONS
Untreated trichomoniasis is associated with pelvic inflammatory disease, premature delivery, low birthweight, tubal infertility, and vaginal cuff cellulitis. T. vaginalis infection increases the risk of acquisition and transmission of HIV. Trichomonas-induced inflammation of the genital mucosa recruits greater numbers of CD4+ cells in the epithelium and provides greater access to the bloodstream for HIV. In HIV-infected individuals, trichomoniasis is associated with higher viral loads in cervical secretions and semen, as well as higher levels of infected lymphocytes in urogenital fluids. HIV-1 shedding in vaginal fluids decreases following treatment for trichomoniasis.

TREATMENT
In the United States, metronidazole and tinidazole are used; in other countries ornidazole is also used. Both metronidazole (single-dose regimen of 2 g orally as a single dose for adolescents and adults; alternative regimen, 500 mg orally bid for 7 days) and tinidazole (single 2 g dose orally in adolescents and adults) are used as first-line treatment. For children infected prior to adolescence, the recommended regimen is metronidazole 15 mg/kg/day divided in 3 doses orally for 7 days; tinidazole is not approved for dosing in younger children. Topical metronidazole gel is not efficacious when used as the sole therapy for T. vaginalis infection, but it may decrease symptoms in individuals with severe infection when used in conjunction with oral therapy. Sexual partners should be treated simultaneously to prevent reinfection. Multiple head-to-head trials comparing the efficacy between single-dose/short courses of metronidazole and single-dose tinidazole have shown either noninferiority or superior efficacy for tinidazole. A Cochrane metaanalysis demonstrated that single dose tinidazole was superior compared to short-course metronidazole in clinical efficacy and parasitologic cure rates and had significantly fewer side effects. Tinidazole is more expensive than metronidazole and is generally reserved for treatment failures or metronidazole intolerance.

Treatment failures have been reported with metronidazole, although poor response can usually be overcome by higher doses of drugs. Second-line treatment recommendations include either a 7-day course of metronidazole 500 mg twice daily or a single dose of tinidazole. If this treatment fails, either metronidazole or tinidazole at 2 g daily for 5 days is recommended. Further treatment failure should be referred to an infectious diseases specialist and may require susceptibility testing, which is available from the Centers for Disease Control and Prevention. Metronidazole has not been shown to be teratogenic during pregnancy in humans but is currently classified as a category C drug. A Cochrane metaanalysis showed an association (RR = 1.78 [1.19, 2.66]) between premature births with metronidazole treatment of asymptomatic T. vaginalis infection in pregnancy. Further studies are needed to confirm this finding. Treatment of symptomatic trichomoniasis in pregnancy should be weighed against possible risks, while treatment of asymptomatic disease should be delayed as much as possible to near term.

PREVENTION
Prevention of T. vaginalis infection is best accomplished by treatment of all sexual partners of an infected person and by programs aimed at prevention of all sexually transmitted infections (see Chapter 120). No vaccine is available, and drug prophylaxis is not recommended.

Bibliography

Martin DH, Zozaya M, Lillis RA, et al: Unique vaginal microbiota which include an unknown Mycoplasma-like organism are associated with Trichomonas vaginalis infection, J Infect Dis 2013.

The leishmaniases are a diverse group of diseases caused by intracellular protozoan parasites of the genus *Leishmania*, which are transmitted by phlebotomine sand flies. Multiple species of *Leishmania* are known to cause human disease involving the skin and mucosal surfaces and the visceral reticuloendothelial organs. Cutaneous disease is generally mild but may cause cosmetic disfigurement. Mucosal and visceral leishmaniasis is associated with significant morbidity and mortality.

**ETIOLOGY**

*Leishmania* organisms are members of the Trypanosomatidae family and include 2 subgenera, *Leishmania (Leishmania)* and *Leishmania (Viannia)*. The parasite is dimorphic, existing as a flagellate promastigote in the insect vector and as an aflagellate amastigote that resides and replicates within mononuclear phagocytes of the vertebrate host. Within the sandfly vector, the promastigote changes from a noninfective procyclic form to an infective metacyclic stage. Fundamental to this transition are changes that take place in the terminal polysaccharides of the surface lipophosphoglycan, which allow forward migration of the infective parasites from the sandfly midgut to the mouth parts and inoculation of the host during a blood meal. Metacyclic lipophosphoglycan also plays an important role in the entry and survival of *Leishmania* in the mammalian host by conferring complement resistance and by facilitating entry into the macrophage by way of multiple receptors, including complement receptors 1 and 3. Once within the macrophage, the promastigote transforms to an amastigote and resides and replicates within a phagolysosome. The parasite is resistant to the acidic, hostile environment of the macrophage and eventually ruptures the cell and goes on to infect other macrophages. Infected macrophages have a diminished capacity to initiate and respond to an inflammatory response, thus providing a safe haven for the intracellular parasite.

**EPIDEMIOLOGY**

The leishmaniases are estimated to affect 10-20 million people in endemic tropical and subtropical regions on all continents except Australia and Antarctica. The different forms of the disease are distinct in their causes, epidemiologic characteristics, transmission, and geographic distribution. The leishmaniases may occur sporadically throughout an endemic region or may occur in epidemic focuses. With only rare exceptions, the *Leishmania* organisms that primarily cause cutaneous disease do not cause visceral disease.  

**Localized cutaneous leishmaniasis (LCL)** in the Old World is caused by *L. (Leishmania) major* and *L. (L.) tropica* in North Africa, the Middle East, central Asia, and the Indian subcontinent. *L. (L.) aethiopica* is a cause of LCL and diffuse cutaneous leishmaniasis (DCL) in Kenya and Ethiopia. **Visceral leishmaniasis (VL)** in the Old World is caused by *L. (L.) donovani* in Kenya, Sudan, India, Pakistan, and China and by *L. (L.) infantum* in the Mediterranean basin, Middle East, and central Asia. *L. infantum* is also a cause of LCL (without visceral disease) in this same geographic distribution. *L. tropica* also has been recognized as an uncommon cause of visceral disease in the Middle East and India. In the New World, *L. (L.) mexicana* causes LCL in a region stretching from southern Texas through Central America. *L. (L.) amazonensis*, *L. (L.) pifanoi*, *L. (L.) garnhami*, and *L. (L.) venezuelensis* cause LCL in South America, the Amazon basin, and northward. Members of the *Viannia* subgenus (*L. [V.] braziliensis*, *L. [V.] panamensis*, *L. [V.] guyanensis*, and *L. [V.] peruviana*) cause LCL from the northern highlands of Argentina northward to Central America.
Members of the Viannia subgenus also cause mucosal leishmaniasis (ML) in a similar geographic distribution. VL in the New World is caused by L. (L.) chagasi (now considered to be the same organism as L. infantum), which is distributed from Mexico (rare) through Central and South America. L. infantum/chagasi can also cause LCL in the absence of visceral disease.

The maintenance of Leishmania in most endemic areas is through a zoonotic transmission cycle. In general, the dermotropic strains in both the Old and New Worlds are maintained in rodent reservoirs, and the domestic dog is the usual reservoir for L. infantum/chagasi. The transmission between reservoir and sandfly is highly adapted to the specific ecologic characteristics of the endemic region. Human infections occur when human activities bring them in contact with the zoonotic cycle. Anthroponotic transmission, in which humans are the presumed reservoir, occurs with L. tropica in some urban areas of the Middle East and Central Asia, and with L. donovani in India and Sudan. Congenital transmission of L. donovani or L. infantum/chagasi has been reported.

There is a resurgence of leishmaniasis in long-standing endemic areas as well as in new foci. Tens of thousands of cases of LCL occurred in an outbreak in Kabul, Afghanistan, and severe epidemics with more than 100,000 deaths from VL have occurred in India and Sudan. VL is most prevalent among the poorest of the poor, with substandard housing contributing to the vector-borne transmission and undernutrition leading to increased host susceptibility. The emergence of the leishmaniasis in new areas is the result of (1) movement of a susceptible population into existing endemic areas, usually because of agricultural or industrial development or timber harvesting; (2) increase in vector and/or reservoir populations as a result of agriculture development projects; (3) increase in anthroponotic transmission owing to rapid urbanization in some focuses; and (4) increase in sandfly density resulting from a reduction in vector control programs.

PATHOLOGY
Histopathologic analysis of the LCL lesion shows intense chronic granulomatous inflammation involving the epidermis and dermis. Occasionally, neutrophils and even macroabscesses can be seen. The lesions of DCL are characterized by dense infiltration with vacuolated macrophages containing abundant amastigotes. ML is characterized by an intense granulomatous reaction with prominent tissue necrosis, which may include adjacent cartilage or bone. In VL there is prominent reticuloendothelial cell hyperplasia in the liver, spleen, bone marrow, and lymph nodes. Amastigotes are abundant in the histiocytes and Kupffer cells. Late in the course of disease, splenic infarcts are common, centrilobular necrosis and fatty infiltration of the liver occur, the normal marrow elements are replaced by parasitized histiocytes, and erythrophagocytosis is present.

PATHOGENESIS
Cellular immune mechanisms determine resistance or susceptibility to infection with Leishmania. Resistance is mediated by interleukin (IL)-12-driven generation of a T helper 1 cell response, with interferon-γ inducing classical macrophage (M1) activation and parasite killing. Susceptibility is associated with expansion of IL-4–producing Th2 cells and/or the production of IL-10 and transforming growth factor-β, which are inhibitors of macrophage-mediated parasite killing, and the generation of regulatory T cells and alternatively activated (M2) macrophages. Patients with ML exhibit a hyperresponsive cellular immune reaction that may contribute to the prominent tissue destruction seen in this form of the disease. Patients with DCL or active VL demonstrate reduced or altered Leishmania-specific cellular immune responses, with prominent generation of IL-10, but these responses recover after successful therapy.

Within endemic areas, people who have had a subclinical infection can be identified by a positive delayed-type hypersensitivity skin response to leishmanial antigens (Montenegro skin test) or by antigen-induced production of interferon-γ in a whole blood assay. Subclinical infection occurs considerably more frequently than does active cutaneous or visceral disease. Host factors (genetic background, concomitant disease, nutritional status), parasite factors (virusulence, size of the inoculum), and possibly vector-specific factors (vector genotype, immunomodulatory salivary constituents) influence the expression as either subclinical infection or active disease. Within endemic areas the prevalence of skin test result positivity increases with age and the incidence of clinical disease decreases with age, indicating that immunity is acquired in the population over time. Individuals with prior active disease or subclinical infection are usually immune to a subsequent clinical infection; however, latent infection can lead to active disease if the patient is immunosuppressed.

CLINICAL MANIFESTATIONS
The different forms of the disease are distinct in their causes, epidemiologic features, transmission, and geographic distribution.

Localized Cutaneous Leishmaniasis
LCL (Oriental sore) can affect individuals of any age, but children are the primary victims in many endemic regions. It may present as 1 or a few papular, nodular, plaquelike, or ulcerative lesions that are usually located on exposed skin, such as the face and extremities (Fig. 285-1). Rarely, more than 100 lesions have been recorded. The lesions typically begin as a small papule at the site of the sandfly bite, which enlarges to 1-3 cm in diameter and may ulcerate over the course of several weeks to months. The shallow ulcer is usually nontender and surrounded by a sharp, indurated, erythematous margin. There is no drainage unless a bacterial superinfection develops. Lesions caused by L. major and L. mexicana usually heal spontaneously after 3-6 mo, leaving a depressed scar. Lesions on the ear pinna caused by L. mexicana, called chiclero ulcer because they were common in chicle harvesters in Mexico and Central America, often follow a chronic, destructive course. In general, lesions caused by L. (Viannia) species tend to be larger and more chronic. Regional lymphadenopathy and palpable subcutaneous nodules or lymphatic cords, the so-called sporotrichoid appearance, are also more common when the patient is infected with organisms of the Viannia subgenus. If lesions do not become secondarily infected, there are usually no complications aside from the residual cutaneous scar.

Diffuse Cutaneous Leishmaniasis
DCL is a rare form of leishmaniasis caused by organisms of the L. mexicana complex in the New World and L. aethiopica in the Old World. DCL manifests as large nonulcerating macules, papules, plaque-like, or nodular lesions (Fig. 285-1). In some cases, DCL can be extensive and involve large portions of the body. The lesions can be solitary or multiple and may be erythematous, hyperkeratotic, or ulcerative. Lesions may be accompanied by lymphadenopathy or regional lymph node enlargement. The clinical course of DCL is variable, and some patients may experience spontaneous regression of lesions without treatment. However, in some cases, DCL can progress to more aggressive forms of cutaneous leishmaniasis, such as mucosal leishmaniasis, disseminated cutaneous leishmaniasis, or systemic infection.

Figure 285-1 Cutaneous disease. A, Old World infection (Leishmania major) acquired in Iraq; note 5 papular and nodular lesions on neck. B, New World infection (Leishmania panamensis) in Colombia; purely ulcerative lesion is characteristic of New World disease. C, Healed infection in patient shown in B 70 days after 20 days of meglumine antimonate treatment; note paper-thin scar tissue over flat reepithelialized skin. (A courtesy of P. Weina. B courtesy of J. Soto. A–C modified from Murray HW, Berman JD, Davies CR, et al: Advances in leishmani- asis, Lancet 366:1561–1577, 2005.)
nodule, or plaques that often involve large areas of skin and may resemble lepromatous leprosy. The face and extremities are most commonly involved. Dissemination from the initial lesion usually takes place over several years. It is thought that an immunologic defect underlies this severe form of cutaneous leishmaniasis.

**Mucosal Leishmaniasis**
ML (espundia) is an uncommon but serious manifestation of leishmanial infection resulting from hematogenous metastases to the nasal or oropharyngeal mucosa from a cutaneous infection. It is usually caused by parasites in the L. (Viannia) complex. Approximately half of the patients with mucosal lesions have had active cutaneous lesions within the preceding 2 yr, but ML may not develop until many years after resolution of the primary lesion. ML occurs in <5% of individuals who have, or have had, LCL caused by L. (V.) braziliensis. Patients with ML most commonly have nasal mucosal involvement and present with nasal congestion, discharge, and recurrent epistaxis. Oropharyngeal and laryngeal involvement is less common but associated with severe morbidity. Marked soft tissue, cartilage, and even bone destruction occurs late in the course of disease and may lead to visible deformity of the nose or mouth, nasal septal perforation, and tracheal narrowing with airway obstruction.

**Visceral Leishmaniasis**
VL (kala-azar) typically affects children younger than 5 yr of age in the New World and Mediterranean region (L. infantum/chagasi) and older children and young adults in Africa and Asia (L. donovani). After inoculation of the organism into the skin by the sandfly, the child may have a completely asymptomatic infection or an oligosymptomatic illness that either resolves spontaneously or evolves into active kala-azar. Children with asymptomatic infection are transiently seropositive but show no clinical evidence of disease. Children who are oligosymptomatic have mild constitutional symptoms (malaise, intermittent diarrhea, poor activity tolerance) and intermittent fever; most will have a mildly enlarged liver. In most of these children the illness will resolve without therapy, but in approximately 25% it will evolve to active kala-azar within 2-8 mo. Extreme incubation periods of several years have rarely been described. During the first few wk to months of disease evolution the fever is intermittent, there is weakness and loss of energy, and the spleen begins to enlarge. The classic clinical features of high fever, marked splenomegaly, hepatomegaly, and severe cachexia typically develop approximately 6 mo after the onset of the illness, but a rapid clinical course over 1 mo has been noted in up to 20% of patients in some series (Fig. 285-2). At the terminal stages of kala-azar the hepatosplenomegaly is massive, there is gross wasting, the pancytope-

---

fever, miliary tuberculosis, schistosomiasis, brucellosis, amebic liver abscess, infectious mononucleosis, lymphoma, and leukemia.

**DIAGNOSIS**

The development of 1 or several slowly progressive, nontender, nodular, or ulcerative lesions in a patient who had potential exposure in an endemic area should raise suspicion of LCL.

Serologic tests for diagnosis of ML or LCL generally have low sensitivity and specificity and offer little for diagnosis. Serologic testing by enzyme immunoassay, indirect fluorescence assay, or direct agglutination is very useful in VL because of the very high level of antileishmanial antibodies. An immunochromatographic strip test using a recombinant antigen (K39) has a diagnostic sensitivity and specificity for VL of 80-90% and 95%, respectively. Serodiagnostic tests have positive findings in only about half of the patients who are coinfected with HIV.

Definitive diagnosis of leishmaniasis is established by the demonstration of amastigotes in tissue specimens or isolation of the organism by culture. Amastigotes can be identified in Giemsa-stained tissue sections, aspirates, or impression smears in about half of the cases of LCL but only rarely in the lesions of ML. Culture of a tissue biopsy or aspirate, best performed by using Novy-McNeal-Nicolle biphasic agar medium, yields a positive finding in only approximately 65% of cases of cutaneous leishmaniasis. Identification of parasites in impression smears, histopathologic sections, or culture medium is more readily accomplished in DCL than in LCL. In patients with VL, smears or cultures of material from splenic, bone marrow, or lymph node aspirations are usually diagnostic. In experienced hands, splenic aspiration has a higher diagnostic sensitivity, but it is rarely performed in the United States because of the risk for bleeding complications. A positive culture result allows speciation of the parasite, usually by isoenzyme analysis by a reference laboratory, which may have therapeutic and prognostic significance.

**TREATMENT**

Specific antileishmanial therapy is not routinely indicated for uncomplicated LCL caused by strains that have a high rate of spontaneous resolution and self-healing (*L. major, L. mexicana*). Lesions that are extensive, severely inflamed, or located where a scar would result in disability (near a joint) or cosmetic disfigurement (face or ear), that involve the lymphatics, or that do not begin healing within 3-4 mo should be treated. Cutaneous lesions suspected or known to be caused by members of the *Vianna* subgenus (New World) should be treated because of the low rate of spontaneous healing and the potential risk for development of mucosal disease. Similarly, patients with lesions caused by *L. tropica* (Old World), which are typically chronic and nonhealing, should be treated. All patients with VL or ML should receive therapy.

The pentavalent antimony compounds (sodium stibogluconate [Pentostam, GlaxoSmithKline, Uxbridge, UK] and meglumine antimoniate [Glucantime, Aventis, Strasbourg, France]) have been the mainstay of antileishmanial chemotherapy for more than 40 yr. These drugs have similar efficacies, toxicities, and treatment regimens. Currently, for sodium stibogluconate (available in the United States from the Centers for Disease Control and Prevention, Atlanta, Georgia), the recommended regimen is 20 mg/kg/day intravenously or intramuscularly for 20 days (for LCL and DCL) or 28 days (for ML and VL). Repeated courses of therapy may be necessary in patients with severe cutaneous lesions, ML, or VL. An initial clinical response to therapy usually occurs in the 1st wk of therapy, but complete clinical healing (reepithelialization and scarring for LCL and ML, and regression of splenomegaly and normalization of cytopenias for VL) is usually not evident for weeks to a few months after completion of therapy. Cure rates with this regimen of 90-100% for LCL, 50-70% for ML, and 80-100% for VL were common in the 1990s, but treatment failures, especially in children, have become common in parts of India, East Africa, and Latin America. Relapses are common in patients who do not have an effective antileishmanial cellular immune response (DCL or HIV coinfection). Adverse effects of antimony therapy are dose and duration dependent and commonly include fatigue, arthralgias and myalgias (50%), abdominal discomfort (30%), elevated hepatic transaminase level (30-80%), elevated amylase and lipase levels (almost 100%), mild hematologic changes (slightly decreased leukocyte count, hemoglobin level, and platelet count) (10-30%), and nonspecific T-wave changes on electrocardiography (30%). Sudden death from cardiac toxicity has rarely been reported with use of very high doses of pentavalent antimony.

Amphotericin B desoxynycholate and the amphotericin lipid formulations are very useful in the treatment of VL or ML and in some regions have replaced antimony as first-line therapy. However, the prohibitively high cost of these drugs precludes their use in many resource-poor regions of the world. Amphotericin B desoxynycholate at doses of 0.5-1.0 mg/kg every day or every other day for 14-20 doses achieved a cure rate for VL of close to 100%, but the renal toxicity associated with amphotericin B was common. The lipid formulations of amphotericin B are especially attractive for treatment of leishmaniasis because the drugs are concentrated in the reticuloendothelial system and are less nephrotoxic. Liposomal amphotericin B is highly effective, with a 90-100% cure rate for VL in immunocompetent children, some of whom were refractory to antimony therapy. Liposomal amphotericin B (AmBisome, Gilead Sciences, Foster City, CA) is approved by the U.S. Food and Drug Administration for treatment of VL at a recommended dose for immunocompetent patients of 3 mg/kg on days 1-5, 14, and 21 and should be considered for first-line therapy in the United States. Therapy for immunocompromised patients may need to be prolonged. A single high dose of liposomal amphotericin B (10 mg/kg) was found to be noninferior to conventional amphotericin (15 doses of 1 mg/kg) in India and offers a less-cost-prohibitive approach. Parenteral treatment of VL with the aminoglycoside paromomycin (aminosidine) has efficacy (~95%) similar to that of amphotericin B in India. Miltefosine, a membrane-activating alkylphospholipid, has been approved as the first oral treatment for VL and has a cure rate of 80-90% in Indian patients with VL when administered orally at 50-100 mg/day (or 2.5 mg/kg for children younger than 12 yr of age) for 28 days. Miltefosine is indicated for cutaneous infection caused by *L. braziliensis, L. guyanensis,* and *L. panamensis*; mucosal disease caused by *L. braziliensis*; and visceral disease caused by *L. donovani.* Gastrointestinal adverse effects were frequent but did not require discontinuation of the drug. An increased rate of relapse (up to 20%) has been seen in children treated with miltefosine. Dose-sparing combination regimens are being actively investigated for treatment of VL. Treatment of LCL with oral drugs has had only modest success. Ketoconazole has been effective in treating adults with LCL caused by *L. major, L. mexicana,* and *L. panamensis,* but not *L. tropica or L. braziliensis.* Fluconazole in high doses (up to 8 mg/kg/day) for 4-8 wk was demonstrated to be effective in treating LCL in studies in both the Old and New World; however, the experience in young children is limited. Miltefosine 2.5 mg/kg/day orally for 20-28 days was effective in 70-90% of patients with LCL in the Americas. Topical treatment of LCL with paromomycin ointment has been effective in selected areas in both Old and New World. Enhanced drug development efforts and clinical trials of new drugs are clearly needed, especially in children.

**PREVENTION**

Personal protective measures should include avoidance of exposure to the nocturnal sandflies and, when necessary, the use of insect repellent and permethrin-impregnated mosquito netting. Where peridomestic arthropod transmission is present, community-based residual insecticide spraying has had some success in reducing the prevalence of leishmaniasis, but long-term effects are difficult to maintain. Control or elimination of infected reservoir hosts (e.g., seropositive domestic dogs) has had limited success. Where anthroponotic transmission is thought to occur, early recognition and treatment of cases are essential. Several vaccines have been demonstrated to have efficacy in experimental models, and vaccination of humans or domestic dogs may have a role in the control of the leishmaniasis in the future.

**Bibliography is available at Expert Consult.**
Bibliography

Seventy million people in 36 countries are at risk for infection with Trypanosoma brucei complex, the causative agent of sleeping sickness. Also known as human African trypanosomiasis (HAT), this disease is restricted to sub-Saharan Africa, the range of the tsetse fly vector. It is a disease of extreme poverty, with an increased burden observed in remote rural areas. HAT comes in 2 geographically and clinically distinct forms. T. brucei gambiense causes a chronic infection lasting years and mostly affects people who live in Western and Central Africa (West African sleeping sickness, Gambian trypanosomiasis). T. brucei rhodesiense is a zoonosis that presents as an acute illness lasting several weeks and usually occurs in residents of eastern and southern Africa (East African sleeping sickness, Rhodesian trypanosomiasis).

**ETIOLOGY**

HAT is a vector-borne disease caused by parasitic, flagellated kinetoplastid protozoans of 2 subspecies of *T. brucei*. It is transmitted to humans through the bite of Glossina, commonly known as the tsetse fly.

The vector feeds on the blood of humans and wild game animals and penetrates intact mucus membranes and skin. Humans usually contract East African HAT when they venture from towns to rural areas to visit woodlands or livestock, highlighting the importance of zoonotic reservoirs in this disease. West African HAT is contracted closer to settlements and only requires a small vector population, making it difficult to eradicate. Low rates of infection in tsetse flies of this form necessitates close and repeated contact between humans and insects to permit frequent biting. While animal reservoirs occur, these are less important than for East African HAT, and the main source of infection remains chronically infected human hosts.

**LIFE CYCLE**

*T. brucei* undergoes several stages of development in the insect and mammalian host. Upon ingestion with a blood meal, nonproliferative stumpy forms of the parasite, which are optimally adapted to the mammalian host, the metacyclic stage transforms into proliferative long and slender forms in the bloodstream and the lymphatics, eventually penetrating the central nervous system. These slender forms appear in waves in the peripheral blood, with each wave followed by a febrile crisis and heralding the formation of a new antigenic variant. The slender forms transform into intermediate forms, which become nonproliferative stumpy forms that are ingested by Glossina and start the cycle anew.

Direct transmission to humans has been reported, either mechanically through contact with the contaminated mouth parts of tsetse flies with viable slender forms during feeding or vertically to infants.

**EPIDEMIOLOGY**

HAT is a major public health problem in sub-Saharan Africa. It occurs in the region between latitudes 14 degrees north and 29 degrees south, corresponding roughly to the area where the annual rainfall creates optimal climatic conditions for *Glossina* flies to thrive. More than 70% of reported cases are from the Democratic Republic of Congo. In 2009, as a result of intensive control efforts spearheaded by the World Health Organization (WHO), the number of new HAT cases annually fell below 10,000 for the first time in 50 yr. In 2011, this further fell to 6,743 cases. As a result, the disease has been targeted by the international community for elimination as a public health problem.

*T. brucei rhodesiense* infection is restricted to the eastern third of the endemic area in tropical Africa, stretching from Ethiopia to the northern boundaries of South Africa. *T. brucei gambiense*, which accounts for 97% of HAT cases, occurs mainly in the western half of the continent’s endemic region. *Glossina* captured in endemic foci show a low rate of infection, usually <5%. Rhodesian HAT, which has an acute and often fatal course, greatly reduces chances of transmission to tsetse flies. The ability of *T. brucei rhodesiense* to multiply rapidly in the bloodstream and infect other species of mammals helps maintain its life cycle. The insect vector is able to transmit disease for up to 6 mo.

**PATHOGENESIS**

The initial entry site of the organisms develops a hard, painful, red nodule known as a trypanosomal chancre. It contains long, thin trypanosomes multiplying beneath the dermis and is surrounded by a lymphocytic cellular infiltrate. Dissemination into the blood and lymphatic systems follows, with subsequent localization to the central nervous system (CNS). Histopathologic findings in the brain are consistent with meningoencephalitis, with lymphocytic infiltration and perivascular cuffing of the membranes. The appearance of morular cells (large, strawberry-like cells, supposedly derived from plasma cells) is a characteristic finding in chronic disease.

Antigenic variation of variant surface glycoproteins on the trypanosome’s surface enables evasion of acquired immunity during infection. Both *T. brucei gambiense* and *T. brucei rhodesiense* have acquired resistance to trypanolytic factors in human serum, the most well-studied of which is apolipoprotein L-1 (APOL1), through the expression of a protein known as serum resistance-associated protein. A frameshift mutation in the APOL1 gene in 1 patient enabled infection with a nonhuman trypanosome, *Trypanosoma evansi*, and treatment with recombinant APOL1 restored trypanolytic activity. Mechanisms underlying virulence in HAT are still incompletely understood, although severity of disease seems to be dependent on the host inflammatory response, particularly interferon-γ production in the CNS and blood.

**CLINICAL MANIFESTATIONS**

Clinical presentations vary not only because of the 2 subspecies of organisms but also because of differences in host response in the indigenous population of endemic areas and in newcomers or visitors. Visitors usually suffer more from the acute symptoms, but in untreated cases death is inevitable for natives and visitors alike. Symptoms usually occur within 1-4 wk of infection. The clinical syndromes of HAT are trypanosomal chancre, hemolymphatic stage, and meningoencephalitic stage.

**Trypanosomal Chancre**

The site of the tsetse fly bite may be the first presenting feature. A nodule or chancre develops in 2-3 days and becomes a painful, hard, red nodule surrounded by an area of erythema and swelling within 1 wk. Nodules are commonly seen on the lower limbs and sometimes also on the head. They subside spontaneously in about 2 wk, leaving no permanent scar.

**Hemolymphatic Stage (Stage 1)**

The most common presenting features of acute HAT occur at the time of invasion of the bloodstream by the parasites, 2-3 wk after infection.
Patients usually present with irregular episodes of fever, each lasting up to 7 days, accompanied by headache, sweating, and generalized lymphadenopathy. Attacks may be separated by symptom-free intervals of days or even weeks. Painless, nonmatted lymphadenopathy, most commonly of the posterior cervical and supraclavicular nodes, is one of the most constant signs, particularly in the Gambian form. A common feature of trypanosomiasis in Caucasians is the presence of blotchy, irregular, nonpruritic, erythematous macules, which may appear any time after the first febrile episode, usually within 6–8 wk. The majority of macules have a normal central area, giving the rash a circinate outline. This rash is seen mainly on the trunk and is evanescent, fading in 1 place only to appear at another site. Examination of the blood during this stage may show anemia, leukopenia with relative monocytosis, and elevated levels of immunoglobulin M. Cardiac manifestations of HAT have also been reported but are generally limited to nonspecific ST-T wave electrocardiographic abnormalities. Histopathologic characterization shows a lymphomonohistiocytic infiltrate in the interstitium and no penetration of the myocardial cells, unlike that for American trypanosomiasis (see Chapter 287). Progression of cardiac pathology to congestive heart failure has not been reported, and the perimyocarditis is usually self-limited and/or readily resolves with treatment.

**Meningoencephalitic Stage (Stage 2)**

Neurologic symptoms and signs are nonspecific, including irritability, insomnia, and irrational and inexplicable anxieties with frequent changes in mood and personality. Neurologic symptoms may precede invasion of the CNS by the organisms. In untreated *T. brucei rhodesiense* infections, CNS invasion occurs within 3–6 wk and is associated with recurrent bouts of headache, fever, weakness, and signs of acute toxemia. Tachycardia may be evidence of myocarditis. Death occurs in 6–9 mo as a result of secondary infection or cardiac failure.

In Gambian HAT, cerebral symptoms appear within 2 yr after the acute symptoms. An increase in drowsiness during the day and insomnia at night reflect the continuous progression of infection and may be accompanied by anemia, leukopenia, and muscle wasting. Patients are also at increased risk for infection.

The chronic, diffuse meningoencephalitis without localizing symptoms is the form referred to as sleeping sickness. Drowsiness and an uncontrollable urge to sleep are the major features of this stage of the disease and become almost continuous in the terminal stages. Tremor or rigidity with stiff and ataxic gait, suggest involvement of the basal ganglia. Psychotic changes occur in almost one third of untreated patients. Although untreated disease has been thought to be uniformly fatal, there is prospective evidence that, in rare cases, some individuals remain asymptomatic, are able to clear parasitemia, and occasionally become seronegative.

**DIAGNOSIS**

Definitive diagnosis can be established during the early stages by examination of a fresh, thick blood smear, which permits visualization of the motile active forms (Fig. 286-1). HAT can also be detected from blood using a variety of sensitive techniques: quantitative buffy coat smears and mini anion exchange resins are common examples. The card agglutination trypanosomiasis test is of value for epidemiologic purposes and in screening for *T. brucei gambiense*. Dried, Giemsa-stained smears should be examined for the detailed morphologic features of the organisms. If a thick blood or buffy coat smear is negative, concentration techniques may help. Aspiration of an enlarged lymph node can also be used to obtain material for parasitologic examination. If positive, cerebrospinal fluid should also be examined for the organisms. The presence of trypanosomes, or 5 white blood cells/µL, or both, is indicative of stage 2 disease. If trypanosomes are absent in the cerebrospinal fluid, some authorities use a count of 20 white blood cells/µL as a cutoff for diagnosing late-stage disease. Because the white blood cell count in the cerebrospinal fluid is critical in making treatment decisions, methods for improving cell counting, such as the use of disposable cell counters and combining multiple counts, have been proposed.

Polymerase chain reaction–based tests have been shown to be highly sensitive and specific, but these require advanced laboratory facilities. Field-based loop-mediated isothermal amplification tests have been developed but need further validation. Low cost, stable, but highly specific rapid tests such as the HAT Sero-Strip and HAT Sero-K-Set that detect trypanosome–specific antibodies have been developed, and may prove to be useful for point-of-care diagnosis as the focus shifts from control to elimination.

**TREATMENT**

The choice of chemotherapeutic agents for treatment is dependent upon the stage of the infection and the causative organisms.

**Stage 1 Treatment**

Hematogenous forms of both Rhodesian and Gambian HAT can be treated with either suramin or pentamidine, which are better tolerated than drugs for stage 2 or CNS disease but are associated with substantial risks of toxicity. Suramin is a polysulphonated symmetrical naphthalene derivative given as a 10% solution for intravenous administration. A test dose (10 mg for children; 100–200 mg for adults) is initially administered to detect rare idiosyncratic reactions of shock and collapse. The dose for subsequent IV injections is 20 mg/kg (maximum: 1 g) administered on days 1, 3, 7, 14, and 21. Suramin is nephrotoxic, and thus a urinalysis should be performed before each dose. Marked proteinuria, blood, or casts is a contraindication to continuation of suramin. Resistance is rare but has been reported.

**Pentamidine isethionate** (4 mg/kg/day IM for 7–10 days daily or on alternate days) concentrates to high levels in trypanosomes and is highly trypanocidal. It is better tolerated than suramin but carries significant risk of hypoglycemia, nephrotoxicity, hypotension, leukopenia, and liver enzyme elevation. Because of its potency, long half-life, and toxicity, short course treatment is desirable and is being investigated.

**Stage 2 Treatment**

The treatment of late stage *T. brucei gambiense* has substantially changed as a result of programmatic efforts of the WHO and the donation of large quantities of trypanosomicidal drugs, including eflornithine, pentamidine, suramin, and nifurtimox. Combination eflornithine and nifurtimox is the treatment of choice for *T. brucei gambiense* CNS infection. This regimen is noninferior to eflornithine monotherapy, and the duration of treatment is shorter. For combination therapy eflornithine is given at 400 mg/kg/day every 12 hr IV for 7 days, along with nifurtimox 15 mg/kg/day every 8 hr PO for 10 days. If nifurtimox is unavailable, eflornithine monotherapy can be given at a dose of 400 mg/kg/day, every 6 hr IV for 14 days. Adverse reactions to these regimens include fever, hypotension and seizures, with combination eflornithine and nifurtimox having less-frequent events.
Melarsoprol is an arsenical compound and is the only effective treatment for late *T. brucei rhodesiense* disease. Treatment of children is initiated at 0.36 mg/kg once daily IV, with gradually escalating doses every 1-5 days to 3.6 mg/kg once daily IV; treatment is usually 10 doses (18-25 mg/kg total dose). Treatment of adults is with melarsoprol 2-3.6 mg/kg once daily IV for 3 days; and after 1 wk, 3.6 mg/kg once daily IV for 3 days, which is repeated after 10-21 days. An alternative regimen is 2.2 mg/kg once daily for 10 days. Guidelines recommend 18-25 mg/kg total over 1 mo. Reactions such as fever, abdominal pain, and chest pain are rare but may occur during or shortly after administration. Serious toxic effects include encephalopathy and exfoliative dermatitis.

Because of the inherent logistic difficulties in administering intravenous therapy for late stage HAT, an active area of research is finding effective oral agents for late-stage HAT. Several promising agents are due to enter phase 2 trials. Efforts to decrease the toxicity of melarsoprol by making it more water soluble are also underway.

**PREVENTION**

A vaccine or consistently effective prophylactic therapy is not available and is particularly challenging because of the antigenic variation resulting from variant surface glycoproteins. A single injection of pentamidine (3-4 mg/kg IM) provides protection against Gambian trypanosomiasis for at least 6 mo, but the effectiveness against the Rhodesian form is uncertain.

While the progress in controlling HAT has been impressive, the increasing cost of treatment per case as the overall number of patients decline may lead to premature termination of intensive control efforts. Underreporting of cases remains a challenge. Vector control programs to control *Glossina* have been essential in controlling disease, coupled with the use of screens, traps, and sanitary measures. Encouraging neutral-colored clothing that is not attractive to the tsetse fly may reduce bites.

Using serology and parasitologic methods, mobile medical surveillance of the population at risk by specialized staff has been done, and strong collaboration between WHO, Medecins sans Frontieres, and African governments has shifted the burden of treatment to well-organized and funded national control programs. Ground spraying of insecticides, aerial spraying, and the use of cloth and live animal baits have proven successful. Transgenic techniques to restrict the ability of the tsetse fly to survive and transmit pathogens are also being developed.

The full genome of *T. brucei* with approximately 9,000 genes has been sequenced. Approximately 10% of these genes encode variant surface glycoproteins. This advance has helped identify genes relevant to the disease and its possible prevention, as well as the design of new antitrypanosomal drugs, including those that target specific metabolic pathways.

*Bibliography is available at Expert Consult.*
Bibliography

American trypanosomiasis or Chagas disease is a vector-borne disease caused by the protozoan \textit{Trypanosoma cruzi}. Its natural vectors are the bloodsucking insects of the family Reduviidae. It can also be transmitted orally from contaminated food, vertically from mother to child, and through blood transfusion and organ transplantation. While acute American trypanosomiasis usually manifests as a nonspecific febrile illness, chronic Chagas disease is associated with cardiomyopathy and severe gastrointestinal abnormalities.

**ETIOLOGY**

American trypanosomiasis is caused by \textit{T. cruzi}, a parasitic, flagellated kinetoplastid protozoan (Fig. 287-1). The main vectors for \textit{T. cruzi} are insects of the order Triatominae, which includes \textit{Triatoma infestans} (free roaming kissing bugs), \textit{Rhodnius prolixus}, and \textit{Panstrongylus megistus}.

**LIFE CYCLE**

\textit{T. cruzi} has 3 recognizable morphogenetic phases: amastigotes, trypomastigotes, and epimastigotes (see Figs. 287-1 and 287-2). Amastigotes are intracellular forms found in mammalian tissues that are spherical and have a short flagellum but form clusters of oval shapes (pseudocysts) within infected tissues. Trypomastigotes are spindle-shaped, extracellular, nondividing forms that are found in blood and are responsible for both transmission of infection to the insect vector and cell-to-cell spread of infection. Epimastigotes are found in the midgut of the vector insect and multiply in the midgut and rectum of arthropods, differentiating into metacyclic trypomastigotes. Metacyclic trypomastigotes are the infectious form for humans and are released onto the skin of a human when the insect defecates close to the site of a bite, entering via the damaged skin or mucous membranes. Once in the host, these multiply intracellularly as amastigotes and are
EPIDEMIOLOGY

Chagas disease is found only in the Western hemisphere, specifically the Americas, particularly in southern Patagonia (Fig. 287-3). Natural transmission only occurs within this region, but the disease may arise elsewhere as a consequence of migration and transmission through contaminated blood. Multilateral efforts coordinated by the World Health Organization and the Pan-American Health Organization in large-scale vector control, blood donor screening to prevent transmission through transfusion, and case-finding and treatment of chronically infected mothers and newborn infants have effectively halted transmission in a number of areas of South America. In the Brazilian Amazon, vectorial transmission from T. infestans has been effectively interrupted through multicountry programs involving vector control, housing design improvements, and health education. The number of cases has dropped from a peak of 24 million in 1984 to a current estimate of 8-10 million. Vectorial transmission continues to drop in other regions, although challenges remain, including the emergence of disease in new areas thought to be Chagas-free, along with occasional re-emergence in previously controlled areas.

Infection is divided into 3 main phases: acute (Table 287-1), indeterminate, and chronic. Acute infection is the most amenable to treatment. Indeterminate infection is asymptomatic but associated with a positive antibody titer. Up to 30% of infected persons proceed to chronic T. cruzi infection and develop symptoms. While it was initially believed that chronic infection without treatment does not clear, at least 3 well-documented cases of spontaneous resolution without treatment have been reported. It is still unclear how this parasitic protozoan escapes the immune system because, unlike African trypanosomiasis (see Chapter 286), antigenic variation is not observed. The T. cruzi genome has been fully sequenced and contains 12,000 genes, the most widely expanded among trypanosomatids, possibly reflect the ability of T. cruzi to invade a wide variety of host tissues. Significant strain-to-strain genome variability and extensive epigenetic modification of surface proteins have been found, likely contributing to immune evasion.

T. cruzi infection is primarily a zoonosis, and humans are incidental hosts. T. cruzi has a large sylvan reservoir and has been isolated from numerous animal species. The presence of reservoirs and vectors of T. cruzi and the socioeconomic and educational levels of the population are the most important risk factors for vector-borne transmission to humans. The arthropod vectors for T. cruzi are the reduviid insects or triatomines, variously known as wild bedbugs, assassin bugs, or kissing bugs. Insect vectors are found in rural, wooded areas and acquire infection through ingestion of blood from humans or animals with circulating trypanomastigotes. Free roaming kissing bugs in the southwestern United States have been found to have fed on humans; some bugs contained T. cruzi.

Housing conditions are very important in the transmission chain. Incidence and prevalence of infection depends on the adaptation of the triatomines to human dwellings as well as the vector capacity of the species. Animal reservoirs of reduviid bugs include dogs, cats, rats, opossums, guinea pigs, monkeys, bats, and raccoons. Humans often
become infected when land in enzootic areas is developed for agricultural or commercial purposes. Although reduviid insects can be found in warmer regions of the United States as far north as Maryland, Chagas disease is extremely rare owing to the higher standard of domestic housing. Most acute cases in the United States are associated with laboratory accidents. An estimated 300,000 immigrants from endemic countries living in the United States are likely infected with *T. cruzi*, 30,000 to 45,000 of whom have cardiomyopathy.

Humans can be infected transplacentally, occurring in 10.5% of infected mothers and causing congenital Chagas disease. Transplacental infection is associated with premature birth, fetal wastage, and placentitis. Previously, up to 1,000 neonates infected with *T. cruzi* were born every year in Argentina; this number has substantially decreased since widespread control programs were initiated. Disease transmission can occur through blood transfusions in endemic areas from asymptomatic blood donors. Seropositivity rates in endemic areas are as high as 20%. The risk for transmission through a single blood transfusion from a chagasic donor is 13-23%. Blood screening for Chagas disease in the United States was started in 2006 and has demonstrated a prevalence of slightly over 1 in 13,000 donors. Risk factors in these donors were consistent with exposure to Chagas disease, including travel to endemic areas and a history of a reduviid bug bite.

Percutaneous injection as a result of laboratory accidents is also a documented mode of transmission. Oral transmission through contaminated food is an increasingly important method of transmission as vector transmission is successfully interrupted by control programs. Although breastfeeding is a very uncommon mode of transmission, women with acute infections should not nurse until they have been treated.

**PATHOGENESIS**

**Acute Disease**

At the site of entry or puncture site, neutrophils, lymphocytes, macrophages, and monocytes infiltrate. *T. cruzi* organisms are engulfed by macrophages and are sequestered in membrane-bound vacuoles. Trypanosomes lyse the phagosomal membrane, escape into the cytoplasm, and replicate. A local tissue reaction, the chagoma, develops, and the process extends to a local lymph node (see Fig. 287-2). Blood forms appear, and the process disseminates. Initial immune recognition of parasites is through innate pathways involving activation of multiple Toll-like receptors (TLRs) by different parasite substrates, including TLR 2/6, TLR 4, and TLR 9. Adaptive immunity is mediated by interferon-γ and interleukin-12 activation of T-cells and is modulated by interleukin-10 and transforming growth factor-β, which downregulates macrophage activity. The interplay of these cytokines is probably responsible, in part, for the variability in disease manifestations and the progression to chronic disease. Acute myocarditis likely occurs in all patients with acute disease but is frequently asymptomatic and may only be apparent on biopsy.

**Chronic Disease**

The pathophysiology of chronic Chagas disease is incompletely understood. Two main mechanisms are likely involved, although other factors may come into play. The first mechanism involves direct tissue destruction by low-level parasite persistence mediated by lymphocytic infiltration and fibrosis. The second mechanism involves molecular mimicry of host antigens by the parasite, resulting in autoantibodies that produce (1) an inflammatory reaction associated with direct damage to host tissue, and/or (2) direct stimulation of adrenergic and muscarinic cholinergic receptors associated with dysautonomia and increased risk of arrhythmia.

*T. cruzi* strains demonstrate selective parasitism for certain tissues. Most strains are myotropic and invade smooth, skeletal, and heart muscle cells. Attachment is mediated by specific receptors on the trypomastigotes that attach to complementary glycoconjugates on the host cell surface. Attachment to cardiac muscle results in inflammation of the endocardium and myocardium, edema, focal necrosis in the contractile and conducting systems, periganglionitis, and lymphocytic inflammation. The heart becomes enlarged, and endocardial thrombosis or aneurysm may result. Right bundle-branch block is also common. Trypanosome parasites also attach to neural cells and reticuloendothelial cells. In patients with gastrointestinal tract involvement, myenteric plexus destruction leads to pathologic organ dilation. Immunologic mechanisms for control of parasitism and resistance are not fully

![Figure 287-3 Estimated number of immigrants with Trypanosoma cruzi infection living in nonendemic countries. Data are supplied for Canada, Australia, and Japan in 2006; the United States in 2005; Spain in 2008, and other European countries in 2004–2006. (From Rassi A Jr, Rassi A, Marin-Neto JA: Chagas disease, Lancet 375:1388–1400, 2010, Fig. 2, p. 1391.)](image-url)
understood. Despite strong acquired immunity, parasitologic cure in chronic infection is exceedingly rare. Antibodies involved with resistance to *T. cruzi* are related to the phase of infection. Immunoglobulin G antibodies, probably to several major surface antigens, mediate immunophagocytosis of *T. cruzi* by macrophages. Conditions that depress cell-mediated immunity increase the severity of *T. cruzi* infection. There is increasing evidence that host genetic factors play a significant role in progression and severity of chronic disease.

**CLINICAL MANIFESTATIONS**

*Acute Chagas disease* in children is usually asymptomatic or is associated with a mild febrile illness characterized by malaise, facial edema, and lymphadenopathy (see Table 287-1). Infants often demonstrate local signs of inflammation at the site of parasite entry, which is then referred to as a *chagoma*. Approximately 50% of children come to medical attention with the *Romaña sign* (unilateral, painless eye swelling), conjunctivitis, and preauricular lymphadenitis. Patients complain of fatigue and headache. Fever can persist for 4-5 wk. More severe systemic presentations can occur in children younger than 2 yr old and may include lymphadenopathy, hepatosplenomegaly, and meningoencephalitis. A cutaneous morbilliform eruption can accompany the acute syndrome. Anemia, lymphocytosis, hepatitis, and thrombocytopenia have also been described.

The heart, central nervous system, peripheral nerve ganglia, and reticuloendothelial system are often heavily parasitized. The heart is the primary target organ. The intense parasitism can result in acute inflammation and in 4-chamber cardiac dilation. Diffuse myocarditis and inflammation of the conduction system can lead to the development of fibrosis. Histologic examination reveals the characteristic pseudocysts, which are the intracellular aggregates of amastigotes.

**Intrauterine infection** in pregnant women can cause spontaneous abortion or premature birth. In children with congenital infection, severe anemia, hepatosplenomegaly, jaundice, and convulsions can mimic congenital cytomegalovirus infection, toxoplasmosis, and erythroblastosis fetalis. *T. cruzi* can be visualized in the cerebrospinal fluid in meningoencephalitis. Children usually undergo spontaneous remission in 8-12 wk and enter an indeterminate phase with lifelong low-grade parasitemia and development of antibodies to many *T. cruzi* cell
Infectious assay (used as a confirmatory test in blood donors in the United States. If granulomatous encephalitis occurs in the acute infection, it is usually fatal.

**Chronic Chagas disease** may be asymptomatic or symptomatic. The most common presentation of chronic *T. cruzi* infection is cardiomyopathy, manifested by congestive heart failure, arhythmia, and thromboembolic events. Electrocardiographic abnormalities include partial or complete atrioventricular block and right bundle-branch block. Left bundle-branch block is unusual. Pathologic examination of infected heart muscle reveals muscle atrophy, myonecrosis, myocytolysis, fibrosis, and lymphocytic infiltration. Myocardial infarction has been reported and may be secondary to left apical aneurysm embolization or necrotizing arteriitis of the microvasculature. Left ventricular apical aneurysms are pathognomonic of chronic chagasic cardiomyopathy.

Gastrointestinal manifestations of chronic Chagas disease occur in 8-10% of patients and involve a diminution in the Auerbach plexus and Meissner plexus. There are also preganglionic lesions and a reduction in the number of dorsal motor nuclear cells of the vagus nerve. Characteristically, this involvement presents clinically as *megaeosophagus* and *megacolon*. Sigmoid dilation, volvulus, and fecalomas are often found in megacolon. Loss of ganglia in the esophagus results in abnormal dilation; the esophagus can reach up to 26 times its normal weight and hold up to 2 L of excess fluid. Megaeosopagus presents as dysphagia, odynophagia, and cough. Esophageal body abnormalities occur independently of lower esophageal dysfunction. Megaeosopagus can lead to esophagitis and cancer of the esophagus. Aspiration pneumonia and pulmonary tuberculosis are also more common in patients with megaeosopagus.

**Immunocompromised Persons**

*T. cruzi* infections in immunocompromised persons may be caused by transmission from an asymptomatic donor of blood products or reactivation of prior infection. Organ donation to allograft recipients can result in a devastating form of the illness. Cardiac transplantation for Chagas cardiomyopathy has resulted in reactivation, despite prophylaxis and postoperative treatment with benznidazole. HIV infection also leads to reactivation in approximately 20% of cases; cerebral lesions are more common in these patients and can mimic those of toxoplasmic encephalitis. Myocarditis is also commonly observed, and secondarily affected lymphatics may be of benefit in some HIV coinfected patients. In immunocompromised patients at risk for reactivation, serologic testing and close monitoring are necessary.

**DIAGNOSIS**

A careful history with attention to geographic origin and travel is important. A *peripheral blood smear* or a Giemsa-stained smear during the acute phase of illness may show motile trypanosomes, which is diagnostic for Chagas disease (see Fig. 287-1). These are only seen in the 1st 6-12 wk of illness. Buffy coat smears may improve yield.

Most persons seek medical attention during the chronic phase of the disease, when parasites are not found in the bloodstream and clinical symptoms are not diagnostic. Serologic testing is used for diagnosis, most commonly enzyme-linked immunosorbent assay, indirect hemagglutination, and indirect fluorescent antibody testing. No single serology test is sufficiently reliable to make the diagnosis, so repeat or parallel testing using a different method or antigen is required to confirm the result of an initial positive serologic test. In the case of discordant results, a third test may be employed. Confirmatory tests used typically include the radiologic immunoprecipitation assay (used as a confirmatory test in blood donors in the United States) and Western blot assays based on trypanomastigote excreted-secreted antigens.

Nonimmunologic methods of diagnosis are also available. Mouse inoculation and xenodiagnosis (allowing uninfected reduviid bugs to feed on a patient's blood and examining the intestinal contents of those bugs 30 days after the meal) are quite sensitive. Parasites may also be cultured in Novy-MacNeal-Nicolle media. Polymerase chain reaction of nuclear and kinetoplast DNA sequences have been developed and can be highly sensitive in acute disease, but are less reliable for the detection of chronic disease. Polymerase chain reaction is not sufficiently sensitive for blood screening and was only positive in 1 of 22 radiologic immunoprecipitation assay-confirmed donors in the United States. Moreover, there is significant variability among methods and parasite strains. An international collaborative study has validated 4 methods that have the best performance characteristics for widespread use. Diagnosis of congenital transmission in newborns cannot be made at birth with serology because of the presence of maternal antibodies in the 1st 6 mo of life. Microscopic examination, parasite culture, or polymerase chain reaction can be used. However, a serologic test at 6-12 mo is recommended to completely exclude infection.

**TREATMENT**

Bioreduction differences between the metabolism of American trypanosomes and that of mammalian hosts have been exploited for chemotherapy. Trypanosomes are very sensitive to oxidative radicals and do not possess catalase or glutathione reductase/glutathione peroxidase, which are key enzymes in scavenging free radicals. All trypanosomes have an unusual reduced nicotinamide adenine dinucleotide phosphate-dependent disulfide reductase. Drugs that stimulate *H₂O₂* generation or prevent its use are potential trypanosomidal agents. Other biochemical pathways that have been targeted include ergosterol synthesis usingazole compounds and the hypoxanthine-guanine phosphoribosyltransferase pathway using allopurinol.

Drug treatment for *T. cruzi* infection is currently limited to nifurtimox and benznidazole. Both are effective against trypanomastigotes and amastigotes and have been used to eradicate parasites in the acute stages of infection. Treatment responses vary according to the phase of Chagas disease, duration of treatment, dose, age of the patient, and geographic origin of the patient. For acute disease, the average cure rate is approximately 60-80%, while for chronic cases, the cure rate is less than 20%. Neither drug is safe in pregnancy.

Benznidazole is a nitroimidazole derivative that may be slightly more effective than nifurtimox. Although benznidazole is capable of inducing the production of free oxide radicals, the dose at which it is given is not effective for this mode of action. Instead, its nitro reduction intermediates may form covalent bonds or interact in other ways with parasitic DNA, lipids, and proteins and cause damage to parasite components. The recommended treatment regimen for children younger than 12 yr of age is 10 mg/kg/day divided twice daily PO for 60 days, and for those older than 12 yr of age, it is 5-7 mg/kg/day divided twice daily PO for 60 days. This drug is associated with significant toxicity, including rash, photosensitivity, peripheral neuritis, granulocytopenia, and thrombocytopenia.

Nifurtimox generates highly toxic oxygen metabolites through the action of nitroreductases, which produce unstable nitro anion radicals, which, in turn, react with oxygen to produce peroxide and superoxide free radicals. The treatment regimen for children 1-10 yr of age is 15-20 mg/kg/day divided 4 times a day PO for 90 days; for children 11-16 yr of age, 12.5-15 mg/kg/day divided 4 times a day PO for 90 days; and for children older than 16 yr of age, 8-10 mg/kg/day divided 3 or 4 times a day PO for 90-120 days. Nifurtimox is associated with weakness, anorexia, gastrointestinal disturbances, toxic hepatitis, tremors, and seizures (hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency).

Although treatment is generally recommended for acute Chagas disease and is effective in the early stages of infection, the treatment of asymptomatic (or indeterminate) infection and symptomatic chronic disease is controversial. Multiple trials with long-term follow-up have yielded mixed results, with an estimated response rate of 6-20% for chronic disease. The definition of response in itself is
problematic, and parasitologic cure is nearly impossible to demonstrate given the limitations of the sensitivity and specificity of detection methods. Instead, serologic conversion is seen as an appropriate treatment response, although some patients who achieve this still eventually develop symptoms. Recommendations from authorities are mixed, with some advocating for treatment regardless of disease phase and others recommending against treatment because of uncertain benefit and the toxicity of the drugs involved. Proponents of the latter approach instead advocate symptomatic treatment of disease manifestations.

Treatment of congestive heart failure is generally in line with recommendations for management of dilated cardiomyopathy from other causes. β-Blockers have been validated in the management of these patients. Digitalis toxicity occurs frequently in patients with Chagas cardiomyopathy. Pacemakers may be necessary in cases of severe heart block. Although cardiac transplantation has been used successfully in chagasic patients, it is reserved for those with the most severe disease manifestations. Plasmapheresis to remove antibodies with adrenergic activity has been proposed for refractory patients, as this approach has been tried and has worked in patients with dilated cardiomyopathy from other causes. However, its application to Chagas disease is unproven.

A light, balanced diet is recommended for megaeosophagus. Surgery or dilation of the lower esophageal sphincter treats megaeosophagus; pneumatic dilation is the superior mode of therapy. Nitrates and nifedipine have been used to reduce lower esophageal sphincter pressure in patients with megaeosophagus. Treatment of megacolon is surgical and symptomatic. Treatment of meningoencephalitis is also supportive.

In accidental infection when parasitic penetration is certain, treatment should be initiated immediately and continued for 10-15 days. Blood is usually collected and tested for seroconversion at 15, 30, and 60 days.

PREVENTION
Massive coordinated vector control programs under the auspices of the World Health Organization and Pan-American Health Organization and the institution of widespread blood donor screening and targeted surveillance of chronically infected mothers and infants at risk have effectively eliminated or at least drastically reduced transmission in most endemic countries. As Chagas disease remains linked to poverty, improvement of living conditions is likewise essential to successful control and eradication. Education of residents in endemic areas, use of bed nets, use of insecticides, and destruction of adobe houses that harbor reduviid bugs are effective methods to control the bug population. Synthetic pyrethroid insecticides help keep houses free of vectors for up to 2 yr and have low toxicity for humans. Paints incorporating insecticides have also been used. A therapeutic vaccine composed of bivalent recombinant *T. cruzi* antigens has been shown to be effective in preclinical proof-of-concept animal models and is currently undergoing further development.

Blood transfusions in endemic areas are a significant risk. Gentian violet, an amphophilic cationic agent that acts photodynamically, has been used to kill the parasite in blood. Photoirradiation of blood containing gentian violet and ascorbate generates free radicals and superoxide anions that are trypanosomicidal. Mepacrine and maprotiline have also been used to eradicate the parasite in blood transfusions.

Because immigrants can carry this disease to nonendemic areas, serologic testing should be performed in blood and organ donors from endemic areas. Potential seropositive donors can be identified by determining whether they have been or have spent extensive time in an endemic area. Questionnaire-based screening of potentially infected blood and organ donors from areas endemic for infection can reduce the risk for transmission. Seropositivity should be considered a contraindication to organ donation, particularly for heart transplantation.

Bibliography is available at Expert Consult.
Bibliography
Malaria is an acute and chronic illness characterized by paroxysms of fever, chills, sweats, fatigue, anemia, and splenomegaly. It has played a major role in human history, causing harm to more people than perhaps any other infectious disease. Malaria is of overwhelming importance in the developing world today, with an estimated 300-500 million cases and more than 1 million deaths each year. Most malarial deaths occur among infants and young children. Although malaria is not endemic in the United States, approximately 1,000 imported cases are recognized in the United States each year. Physicians practicing in nonendemic areas should consider the diagnosis of malaria in any febrile child who has returned from a malaria-endemic area within the previous year, because delay in diagnosis and treatment can result in severe illness or death.

**ETIOLOGY**

Malaria is caused by intracellular *Plasmodium* protozoa transmitted to humans by female *Anopheles* mosquitoes. Prior to 2004, only 4 species of *Plasmodium* were known to cause malaria in humans: *P. falciparum*, *P. malariae*, *P. ovale*, and *P. vivax*. In 2004 *P. knowlesi* (a primate malaria species) was also shown to cause human malaria, and cases of *P. knowlesi* infection have been documented in Malaysia, Indonesia, Singapore, and the Philippines. Malaria also can be transmitted through blood transfusion, use of contaminated needles, and transplacentally from a pregnant woman to her fetus. The risk for blood transmission is small and decreasing in the United States, but may occur by way of whole blood, packed red blood cells, platelets, leukocytes, and organ transplantation.

**EPIDEMIOLOGY**

Malaria is a major worldwide problem, occurring in more than 100 countries with a combined population of more than 1.6 billion people (Fig. 288-1). The principal areas of transmission are Africa, Asia, and South America. *P. falciparum* and *P. malariae* are found in most malarious areas. *P. falciparum* is the predominant species in Africa, Haiti, and New Guinea. *P. vivax* predominates in Bangladesh, Central America, India, Pakistan, and Sri Lanka. *P. vivax* and *P. falciparum* predominate in Southeast Asia, South America, and Oceania. *P. ovale* is the least-common species and is transmitted primarily in Africa. Transmission of malaria has been eliminated in most of North America (including the United States), Europe, and the Caribbean, as well as Australia, Chile, Israel, Japan, Korea, Lebanon, and Taiwan.

Most cases of malaria in the United States occur among previously infected visitors to the United States from endemic areas and among U.S. citizens who travel to endemic areas without appropriate chemoprophylaxis. The most common regions of acquisition of the 10,100 cases of malaria reported to the Centers for Disease Control and Prevention (CDC) among U.S. citizens between 1985 and 2001 were sub-Saharan Africa (58%), Asia (18%), and the Caribbean and Central or South America (16%). Most of the fatal cases were caused by *P. falciparum* (94% or 66 of the 70 cases), of which 47 (71%) were acquired in sub-Saharan Africa. More than 60% of imported cases of *P. vivax* come from Asia; the remaining species usually come from Africa. Rare cases of apparent locally transmitted malaria have been reported since the 1950s. These cases are likely a result of transmission from untreated and often asymptomatic infected individuals from malaria endemic countries who travel to the United States and infect local mosquitoes or to infected mosquitoes from malaria-endemic areas that are transported to the United States on airplanes.
Pathogenesis

Plasmodium species exist in a variety of forms and have a complex life cycle that enables them to survive in different cellular environments in the human host (asexual phase) and the mosquito (sexual phase) (Fig. 288-2). A marked amplification of Plasmodium, from approximately $10^2$ to as many as $10^{20}$ organisms, occurs during a 2-step process in humans, with the first phase in hepatic cells (exoerythrocytic phase) and the second phase in the red cells (erythrocytic phase). The exo-erythrocytic phase begins with inoculation of sporozoites into the bloodstream by a female Anopheles mosquito. Within minutes, the sporozoites enter the hepatocytes of the liver, where they develop and multiply asexually as a schizont. After 1-2 wk, the hepatocytes rupture and release thousands of merozoites into the circulation. The tissue schizonts of P. falciparum, P. malariae, and apparently P. knowlesi rupture once and do not persist in the liver. There are 2 types of tissue schizonts for P. ovale and P. vivax. The primary type ruptures in 6-9 days, and the secondary type remains dormant in the liver cell for weeks, months, or as long as 5 yr before releasing merozoites and causing relapse of infection. The erythrocytic phase of Plasmodium asexual development begins when the merozoites from the liver penetrate erythrocytes. Once inside the erythrocyte, the parasite transforms into the ring form, which then enlarges to become a trophozoite. These latter 2 forms can be identified with Giemsa stain on blood smear, the primary means of confirming the diagnosis of malaria (Fig. 288-3). The trophozoite multiplies asexually to produce a number of small erythrocytic merozoites that are released into the bloodstream when the erythrocyte membrane ruptures, which is associated with fever. Over time, some of the merozoites develop into male and female gametocytes that complete the Plasmodium life cycle when they are ingested during a blood meal by the female anopheline mosquito. The male and female gametocytes fuse to form a zygote in the stomach cavity of the mosquito. After a series of further transformations, merozoites enter the salivary gland of the mosquito and are inoculated into a new host with the next blood meal.

Four important pathologic processes have been identified in patients with malaria: fever, anemia, immunopathologic events, and tissue anoxia. Fever occurs when erythrocytes rupture and release merozoites into the circulation. Anemia is caused by hemolysis, sequestration of erythrocytes in the spleen and other organs, and bone marrow suppression. Immunopathologic events that have been documented in patients with malaria include excessive production of proinflammatory cytokines, such as tumor necrosis factor, that may be responsible for most of the pathology of the disease, including tissue anoxia; polyclonal activation resulting in both hypergammaglobulinemia and the formation of immune complexes; and immunosuppression. Cytoadherence of infected erythrocytes to vascular endothelium occurs in P. falciparum malaria and may lead to obstruction of blood flow and capillary damage, with resultant vascular leakage of blood, protein, and fluid and tissue anoxia. In addition, hypoglycemia and lactic acidemia are caused by anaerobic metabolism of glucose. The cumulative effects of these pathologic processes may lead to cerebral, cardiac, pulmonary, intestinal, renal, and hepatic failure.

Immunity after Plasmodium species infection is incomplete, preventing severe disease but still allowing future infection. In some cases, parasites circulate in small numbers for a long time but are prevented from rapidly multiplying and causing severe illness. Repeated episodes of infection occur because the parasite has developed a number of immune evasive strategies, such as intracellular replication, vascular cytoadherence that prevents infected erythrocytes from circulating through the spleen, rapid antigenic variation, and alteration of the host immune system resulting in partial immune suppression. The human host response to Plasmodium infection includes natural immune mechanisms that prevent infection by other Plasmodium species, such as those of birds or rodents, as well as several alterations in erythrocyte physiology that prevent or modify malarial infection. Erythrocytes containing hemoglobin S (sickle erythrocytes) resist malaria parasite growth, erythrocytes lacking Duffy blood group antigen are resistant to P. vivax, and erythrocytes containing hemoglobin F (fetal hemoglobin) and ovalocytes are resistant to P. falciparum. In hyperendemic areas, newborns rarely become ill with malaria, in part because of passive maternal antibody and high levels of fetal hemoglobin. Children 3 mo to 2-5 yr of age have little specific immunity to malaria species and therefore suffer yearly attacks of debilitating and potentially fatal disease. Immunity is subsequently acquired, and severe cases of malaria become less common. Severe disease may occur during pregnancy, particularly first pregnancies or after extended residence outside the endemic region. In general, extracellular Plasmodium organisms are targeted by antibody, whereas intracellular organisms are targeted by cellular defenses such as T lymphocytes, macrophages, polymorphonuclear leukocytes, and the spleen.

Figure 288-1 Global spatial distribution of Plasmodium falciparum malaria in 2007 and preliminary global distribution of Plasmodium vivax malaria. (From Crawley J, Chu C, Mtove G, et al: Malaria in children, Lancet 375:1468-1478, 2010, Fig. 1, p. 1469.)
Figure 288-2 Life cycle of *Plasmodium* spp. (From Centers for Disease Control and Prevention [CDC]; Laboratory diagnosis of malaria: Plasmodium spp. Available at: http://www.dpd.cdc.gov/dpdx/HL/ImageLibrary/M-R/Malaria/body_Malaria_il1.h)

Figure 288-3 Giemsa-stained thick (A) and thin (B-H) smears used for the diagnosis of malaria and the speciation of *Plasmodium* parasites. A, Multiple signet-ring *Plasmodium falciparum* trophozoites, which are visualized outside erythrocytes. B, A multiply infected erythrocyte containing signet-ring *P. falciparum* trophozoites, including an accolade form positioned up against the inner surface of the erythrocyte membrane. C, Banana-shaped gametocyte unique to *P. falciparum*. D, Ameboid trophozoite characteristic of *Plasmodium vivax*. Both *P. vivax*– and *Plasmodium ovale*–infected erythrocytes exhibit Schüffner dots and tend to be enlarged compared with uninfected erythrocytes. E, *P. vivax* schizont. Mature *P. falciparum* parasites, by contrast, are rarely seen on blood smears because they sequester in the systemic microvasculature. F, *P. vivax* spherical gametocyte. G, *P. ovale* trophozoite. Note Schüffner dots and ovoid shapes of the infected erythrocyte. H, Characteristic band form trophozoite of *Plasmodium malariae*, containing intracellular pigment hemozoin. (A, B, and F from Centers for Disease Control and Prevention [CDC]; DPDx: laboratory identification of parasites of public health concern. Available at: http://www.dpd.cdc.gov/dpdx/. CLINICAL MANIFESTATIONS

Children and adults are asymptomatic during the initial phase of infection, the incubation period of malaria infection. The usual incubation periods are 9–14 days for *P. falciparum*, 12–17 days for *P. vivax*, 16–18 days for *P. ovale*, and 18–40 days for *P. malariae*. The incubation period can be as long as 6–12 mo for *P. vivax* and can also be prolonged for patients with partial immunity or incomplete chemoprophylaxis. A prodrome lasting 2–3 days is noted in some patients before parasites are detected in the blood. Prodromal symptoms include headache, fatigue, anorexia, myalgia, slight fever, and pain in the chest, abdomen, and joints.

The classic presentation of malaria is seldom noted with other infectious diseases and consists of paroxysms of fever alternating with periods of fatigue but otherwise relative well-being. Febrile paroxysms are characterized by high fever, sweats, and headache, as well as myalgia, back pain, abdominal pain, nausea, vomiting, diarrhea, pallor, and jaundice. Paroxysms coincide with the rupture of schizonts that occurs every 48 hr with *P. vivax* and *P. ovale*, resulting in fever spikes every other day. Rupture of schizonts occurs every 72 hr with *P. malariae*, resulting in fever spikes every third or fourth day. Periodicity is less apparent with *P. falciparum* and mixed infections and may not be apparent early on in infection, when parasite broods have not yet synchronized. Patients with primary infection, such as travelers from nonendemic regions, also may have irregular symptomatic episodes for 2–3 days before regular paroxysms begin. Children with malaria often lack typical paroxysms and have nonspecific symptoms, including fever (may be low-grade but is often greater than 40°C [104°F]), headache, drowsiness, anorexia, nausea, vomiting, and diarrhea. Distinctive physical signs may include splenomegaly (common), hepatomegaly, and pallor as a consequence of anemia. Typical laboratory findings include anemia, thrombocytopenia, and a normal or low leukocyte count. The erythrocyte sedimentation rate is often elevated.

*P. falciparum* is the most severe form of malaria and is associated with higher density parasitemia and a number of complications (Fig. 288-4). The most common serious complication is severe anemia, which also is associated with other malaria species. Serious complications that appear unique to *P. falciparum* include cerebral malaria, acute renal failure, respiratory distress from metabolic acidosis, algid malaria and bleeding diatheses (see “Complications of *Plasmodium falciparum* Malaria” below and Table 288-1). The diagnosis of *P. falciparum* malaria in a nonimmune individual constitutes a medical emergency. Severe complications and death can occur if appropriate therapy is not instituted promptly. In contrast to malaria caused by *P. ovale* and *P. vivax*, which usually results in parasitemias of less than 2%, malaria caused by *P. falciparum* can be associated with parasitemia levels as high as 60%. The differences in parasitemia reflect the fact that *P. falciparum* infects both immature and mature erythrocytes, whereas *P. ovale* and *P. vivax* primarily infect immature erythrocytes and *P. malariae* infects only mature erythrocytes. Like *P. falciparum*, *P. knowlesi* has a 24 hr replication cycle and can also lead to very-high-density parasitemia.

*P. vivax* malaria has long been considered less severe than *P. falciparum* malaria, but recent reports suggest that in some areas of Indonesia it is as frequent a cause of severe disease and death as *P. falciparum*. Severe disease and death from *P. vivax* are usually a consequence of severe anemia and sometimes of splenic rupture. *P. ovale* malaria is the least-common type of malaria. It is similar to *P. vivax* malaria and commonly is found in conjunction with *P. falciparum* malaria. *P. malariae* is the mildest and most chronic of all malaria infections. Nephrotic syndrome is a rare complication of *P. malariae* infection that is not observed with any other human malaria species. Nephrotic syndrome associated with *P. malariae* infection is poorly responsive to steroids. Low-level, undetected *P. malariae* infection may be present for years and is sometimes unmasked by immunosuppression or physiologic stress such as splenectomy or corticosteroid treatment.

Recrudescent malaria after a primary attack may occur from the survival of erythrocyte forms in the bloodstream. Long-term relapse is caused by release of merozoites from an exoerythrocytic source in the liver, which occurs with *P. vivax* and *P. ovale*, or from persistence within the
erythrocyte, which occurs with *P. malariae* and rarely with *P. falciparum*. A history of typical symptoms in a person more than 4 wk after return from an endemic area is therefore more likely to be *P. vivax*, *P. ovale*, or *P. malariae* infection than *P. falciparum* infection. In the most recent survey of malaria in the United States among individuals in whom a malaria species was identified, 48.6% of cases were caused by *P. falciparum*, 22.1% by *P. vivax*, 3.5% by *P. malariae*, and 2.5% by *P. ovale*. Ninety-four percent of *P. falciparum* infections were diagnosed within 30 days of arrival in the United States, and 99% within 90 days of arrival. In contrast, 50.7% of *P. vivax* cases occurred more than 30 days after arrival in the United States.

**Congenital malaria** is acquired from the mother prenatally or perinatally and is a serious problem in tropical areas but is rarely reported in the United States. In endemic areas, congenital malaria is an important cause of abortions, miscarriages, stillbirths, premature births, intrauterine growth retardation, and neonatal deaths. Congenital malaria usually occurs in the offspring of a nonimmune mother with *P. vivax* or *P. malariae* infection, although it can be observed with any of the human malaria species. The first sign or symptom most commonly occurs between 10 and 30 days of age (range: 14 hr to several months of age). Signs and symptoms include fever, restlessness, drowsiness, pallor, jaundice, poor feeding, vomiting, diarrhea, cyanosis, and hepatosplenomegaly. Malaria is often severe during pregnancy and may have an adverse effect on the fetus or neonate, resulting in intrauterine growth retardation and low birthweight, even in the absence of transmission from mother to child.

**DIAGNOSIS**

Any child who presents with fever or unexplained systemic illness and has traveled or resided in a malaria-endemic area within the previous year should be assumed to have life-threatening malaria until proven otherwise. Malaria should be considered regardless of the use of chemoprophylaxis. Important criteria that suggest *P. falciparum* malaria include symptoms occurring less than 1 mo after return from an endemic area, more than 2% parasitemia, ring forms with double chromatin dots, and erythrocytes infected with more than 1 parasite.

The diagnosis of malaria is established by identification of organisms on Giemsa-stained smears of peripheral blood (see Fig. 288-3) or by rapid immunochromatographic assay (rapid diagnostic test). Giemsa stain is superior to Wright stain or Leishman stain. Both thick and thin blood smears should be examined. The concentration of erythrocytes on a **thick smear** is 20-40 times that on a thin smear and is used to quickly scan large numbers of erythrocytes. The **thin smear** allows for positive identification of the malaria species and determination of the percentage of infected erythrocytes and is useful in following the response to therapy. Identification of the species is best made by an experienced microscopist and checked against color plates of the various *Plasmodium* species (see Fig. 288-3). Morphologically it is impossible to distinguish *P. knowlesi* from *P. malariae*, so polymerase chain reaction detection by a reference lab or the CDC is required. Although *P. falciparum* is most likely to be identified from blood just after a febrile paroxysm, the timing of the both thick and thin smears is less important than their being obtained several times a day over a period of 3 successive days. A single negative blood smear does not exclude malaria. Most symptomatic patients with malaria will have detectable parasites on thick blood smears within 48 hr. For nonimmune persons, symptoms typically occur 1-2 days before parasites are detectable on blood smear.

The BinaxNOW Malaria test is approved by the FDA for rapid diagnosis of malaria. This immunochromatographic test for *P. falciparum* histidine-rich protein (HRP2) and aldolase is approved for testing for *P. falciparum* and *P. vivax*. Aldolase is present in all 5 of the malaria species that infect humans. Thus, a positive result for *P. vivax* could be because of *P. ovale* or *P. malariae* infection. Sensitivity and specificity for *P. falciparum* (94-99% and 94-99%, respectively) and *P. vivax* (87-93% and 99%, respectively) are good, but sensitivity for *P. ovale* and *P. malariae* is lower. Sensitivity for *P. falciparum* decreases at lower levels of parasitemia, so microscopy is still advised in areas where expert microscopy is available. The test is simple to perform and can be done in the field or laboratory in 10 min. Polymerase chain reaction is even more sensitive than microscopy but is technically more complex. It is available in some reference laboratories, but the time delay in availability of results generally precludes its use for acute diagnosis of malaria.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of malaria is broad and includes viral infections such as influenza and hepatitis, sepsis, pneumonia, meningitis, encephalitis, endocarditis, gastroenteritis, pylonephritis, babesiosis, brucellosis, leptospirosis, tuberculosis, relapsing fever, typhoid fever, yellow fever, viral hemorrhagic fevers, amebic liver abscess, Hodgkin disease, and collagen vascular disease.

**TREATMENT**

Physicians caring for patients with malaria or traveling to endemic areas need to be aware of current information regarding malaria because resistance to antimalarial drugs has complicated therapy and prophylaxis. The best source for such information is the CDC Malaria webpage (http://www.cdc.gov/malaria/diagnosis_treatment/treatment.html), which provides up-to-date guidelines for malaria treatment, and an algorithm for an approach to malaria treatment (Fig. 288-5). In cases in which treatment is unclear or complex, the CDC Malaria Hotline, which is available to physicians 24 hr a day (770-488-7788 from 8:00 AM to 4:30 PM Eastern Standard Time [EST] and 770-488-7100 from 4:30 PM to 8:00 AM EST, and on weekends and holidays; ask the operator to page the person on call for the Malaria Epidemiology Branch), is an excellent resource.

Fever without an obvious cause in any patient who has left a *P. falciparum* endemic area within 30 days and is nonimmune should be considered a medical emergency. Thick and thin blood smears should be obtained immediately, and all children with symptoms of severe disease should be hospitalized. If blood films are negative, they should be repeated every few hours. If the patient is severely ill, antimalarial therapy should be initiated immediately. Outpatient therapy generally is not given to nonimmune children but may be considered in immune or semi-immune children who have low-level parasitemia (<1%), no evidence of complications defined by the World Health Organization, no vomiting, and a lack of toxic appearance; who are able to contact the physician or emergency department at any time; and in whom follow-up within 24 hr is assured.

**Plasmodium Falciparum Malaria**

Malarious regions considered chloroquine-sensitive include Central America west of the Panama Canal, Haiti, the Dominican Republic, and most of the Middle East except Iran, Oman, Saudi Arabia, and Yemen. The CDC website (http://www.cdc.gov/MMALARIA/) should be consulted for updated information on chloroquine susceptibility in an area, and current treatment options. Individuals traveling from areas with chloroquine-susceptible *P. falciparum* can be treated with chloroquine if they do not have severe malaria. Malaria acquired in *P. falciparum* areas with chloroquine resistance or where there is any doubt about chloroquine sensitivity after conferring with the CDC should be treated with drugs other than chloroquine (Table 288-2). Trials in Asia and Africa have definitively proven that artesunate treatment of severe malaria is associated with decreased mortality when compared to quinine treatment. However, artesunate is still not FDA approved in the United States for treatment of malaria, or available outside of special request indications from the CDC, so intravenous quinidine gluconate remains first-line therapy for severe malaria in the United States (Table 288-2). Monotherapy with artesunate agents is discouraged because of the development of resistance and treatment failures. Nonetheless in endemic countries, artesunate derivatives in combination with other antimalarial agents have become the treatment of choice (Tables 288-3 and 288-4). Children with severe malaria should be admitted to the intensive care unit for monitoring of complications, plasma quinidine levels, and adverse effects during quinidine administration. During administration of quinidine, blood pressure monitoring for hypotension and cardiac monitoring for widening of the QRS complex.

Total dose = 1,250 mg salt | **D. Mefloquine (Lariam and generics)**<sup>7</sup>  
13.7 mg base/kg (=15 mg salt/kg) PO as initial dose, followed by 9.1 mg base/kg (=10 mg salt/kg) PO given 6-12 hr after initial dose. Total dose = 25 mg salt/kg |

<sup>1</sup>If a person develops malaria despite taking chemoprophylaxis, that particular medicine should not be used as a part of their treatment regimen. Use 1 of the other options instead.

<sup>2</sup>NOTE: There are 4 options (A, B, C, or D) available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. falciparum*. Options A, B, and C are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, we do not recommend option D (mefloquine) unless the other options cannot be used. For option C, because there is more data on the efficacy of quinine in combination with doxycycline or tetracycline, these treatment combinations are generally preferred to quinine in combination with clindamycin.

<sup>3</sup>Take with food or half milk. If patient vomits within 30 min of taking a dose, then patient should repeat the dose.

<sup>4</sup>U.S. manufactured quinine sulfate capsule is in a 324 mg dosage; therefore 2 capsules should be sufficient for adult dosing. Pediatric dosing may be difficult because of unavailability of noncapsule forms of quinine.

<sup>5</sup>For infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired elsewhere, quinine treatment should continue for 3 days.

<sup>6</sup>Doxycycline and tetracycline are not indicated for use in children younger than 8 yr old. For children younger than 8 yr old with chloroquine-resistant *P. falciparum*, atovaquone-proguanil and artemether-lumefantrine are recommended treatment options; mefloquine can be considered if no other options are available. For children younger than 8 yr old with chloroquine-resistant *P. vivax*, mefloquine is the recommended treatment. If it is not available or is being tolerated and if the treatment benefits outweigh the risks, atovaquone-proguanil or artemether-lumefantrine should be used instead.

<sup>7</sup>Treatment with mefloquine is not recommended in persons who have acquired infections from Southeast Asia as a consequence of drug resistance.

<sup>8</sup>When treating chloroquine-sensitive infections, chloroquine and hydroxychloroquine are recommended options. However, regimens used to treat chloroquine-resistant infections may also be used if available, more convenient, or preferred.

**Chapter 288 ♦ Malaria (Plasmodium)**
**Uncomplicated malaria/P. falciparum**

Chloroquine phosphate: treatment as above or Hydroxychloroquine: treatment as above

**Uncomplicated malaria/P. vivax**

A. Quinine sulfate plus either doxycycline or tetracycline plus primaquine phosphate
   - Quinine sulfate: treatment as above
   - Doxycycline or tetracycline: Treatment as above
   - Primaquine phosphate: treatment as above

B. Atovaquone-proguanil plus primaquine phosphate
   - Atovaquone-proguanil: treatment as above
   - Primaquine phosphate: treatment as above

C. Mefloquine plus primaquine phosphate
   - Mefloquine: treatment as above
   - Primaquine phosphate: treatment as above

**Uncomplicated malaria/P. knowlesi or P. ovale**

Chloroquine phosphate: treatment as above or Hydroxychloroquine: treatment as above

**Uncomplicated malaria/P. vivax**

Chloroquine-resistant (Papua New Guinea and Indonesia)

A. Quinine sulfate plus either doxycycline or tetracycline plus primaquine phosphate
   - Quinine sulfate: treatment as above
   - Doxycycline or tetracycline: Treatment as above
   - Primaquine phosphate: treatment as above

B. Atovaquone-proguanil plus primaquine phosphate
   - Atovaquone-proguanil: treatment as above
   - Primaquine phosphate: treatment as above

C. Mefloquine plus primaquine phosphate
   - Mefloquine: treatment as above
   - Primaquine phosphate: treatment as above

**Uncomplicated malaria: alternatives for pregnant women**

Chloroquine-resistant (See sections above for regions with chloroquine-resistant P. falciparum and P. vivax)

Quinine sulfate plus clindamycin
   - Quinine sulfate: treatment as above
   - Clindamycin: treatment as above

Mefloquine: treatment as above

**Primaquine is used to eradicate any hypnozoites that may remain dormant in the liver, and thus prevent relapses, in P. vivax and P. ovale infections. Because primaquine can cause hemolytic anemia in glucose-6-phosphate dehydrogenase (G6PD)-deficient persons, G6PD screening must occur prior to starting treatment with primaquine. For persons with borderline G6PD deficiency or as an alternate to the above regimen, primaquine may be given 45 mg base PO qd x 14 days. Primaquine must not be used during pregnancy.**

**NOTE:** There are 3 options (A, B, or C) available for treatment of uncomplicated malaria caused by chloroquine-resistant P. vivax. High treatment failure rates as a result of chloroquine-resistant P. vivax are well documented in Papua New Guinea and Indonesia. Rare case reports of chloroquine-resistant P. vivax are also documented in Burma (Myanmar), India, and Central and South America. Persons acquiring P. vivax infections outside of Papua New Guinea or Indonesia should be started on chloroquine. If the patient does not respond, the treatment should be changed to a chloroquine-resistant P. vivax regimen and CDC should be notified (Malaria Hotline number listed above). For treatment of chloroquine-resistant P. vivax infections, options A, B, and C are equally recommended.

**For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant P. falciparum or chloroquine-resistant P. vivax infection, treatment with doxycycline or tetracycline is generally not indicated. However, doxycycline or tetracycline may be used in combination with quinine (as recommended for non-pregnant adults) if other treatment options are not available or are not being tolerated, and the benefit is judged to outweigh the risks.**

**For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant P. falciparum infection, atovaquone-proguanil or artemether-lumefantrine may be used if other treatment options are not available or are not being tolerated, and if the potential benefit is judged to outweigh the potential risks.**

**For P. vivax and P. ovale infections, primaquine phosphate for radical treatment of hypnozoites should not be given during pregnancy. Pregnant patients with P. vivax and P. ovale infections should be maintained on chloroquine prophylaxis for the duration of their pregnancy. The chemoprophylactic dose of chloroquine phosphate is 300 mg base (=500 mg salt) orally once per week. After delivery, pregnant patients who do not have G6PD deficiency should be treated with primaquine.**

14Persons with a positive blood smear or history of recent possible exposure and no other recognized pathology who have 1 or more of the following clinical criteria (impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, and/or parasitemia of >5%) are considered to have manifestations of more severe disease. Severe malaria is most often caused by *P. falciparum*.

15Patients diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy. Treatment with IV quinidine should be initiated as soon as possible after the diagnosis has been made. Patients with severe malaria should be given an intravenous loading dose of quinidine unless they have received more than 40 mg/kg of quinine in the preceding 48 hr or if they have received mefloquine within the preceding 12 hr. Consultation with a cardiologist and a physician with experience treating malaria is advised when treating malaria patients with quinidine. During administration of quinidine, blood pressure monitoring (for hypotension) and cardiac monitoring (for widening of the QRS complex and/or lengthening of the QTc interval) should be monitored continuously and blood glucose (for hypoglycemia) should be monitored periodically. Cardiac complications, if severe, may warrant temporary discontinuation of the drug or slowing of the intravenous infusion.

16Pregnant women diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy.

complex or lengthening of the QTc interval should be performed continuously, and blood glucose monitoring for hypoglycemia should be performed periodically. Cardiac adverse events may require temporary discontinuation of the drug or slowing of the intravenous infusion. Parenteral therapy should be continued until the parasitemia is less than 1%, which usually occurs within 48 hr, and the patient can tolerate oral medication. Quinidine gluconate (United States) or quinine sulfate (other countries) is administered for a total of 3 days for malaria acquired in Africa or South America and for 7 days for malaria acquired in Southeast Asia. Doxycycline, tetracycline, or clindamycin is then given orally to complete the therapeutic course (see Tables 288-2 and 288-4). Although there are no data to support the use of sequential quinine and atovaquone-proguanil, the difficulty of maintaining compliance with oral quinine has led many clinicians to complete oral therapy after IV quinine with a complete course of atovaquone-proguanil.

Parenterally administered artesunate or artemether can be substituted for quinine for treatment of severe malaria in children and adults (see Table 288-2). Artesunate is now available on special request from the CDC (770-488-7788) for treatment of severe malaria, but empirical therapy should not be delayed while awaiting delivery of artesunate. Children who do receive artesunate can follow up with

*World Health Organization prequalified fixed dose formulations are preferable to loose tablets. A taste masked dispersible pediatric tablet formulation of artemether-lumefantrine is available.

†High failure rates with artemesate-mefloquine have been reported on the Thailand-Myanmar border.

‡Any of the artemisinin combination treatments can be given except for artesunate-sulfadoxine-pyrimethamine where P. vivax is resistant. Patients with P. vivax or P. ovale infections should also be given a 14 day course of primaquine to eradicate hypnozoites (radical cure). However, severe glucose-6-phosphate dehydrogenase deficiency is a contraindication because a 14 day course of primaquine can cause severe hemolytic anemia in this group.

**Table 288-4** Treatment of Severe Malaria in Adults and Children

- Artesunate 2.4 mg/kg by intravenous or intramuscular* injection, followed by 2.4 mg/kg at 12 hr and 24 hr, continue injection once daily if necessary†
- Artemether 3.2 mg/kg by immediate intramuscular* injection, followed by 1.6 mg/kg daily
- Quinine dihydrochloride 20 mg salt per kg infused during 4 hr, followed by maintenance of 10 mg salt per kg infused during 2-8 hr every 8 hr (can also be given by intramuscular injection* when diluted to 60-100 mg/mL)
- Artesunate is the treatment of choice. Artemether should only be used if artesunate is unavailable. Quinine dihydrochloride should be given only when artemether and artesunate are unavailable.

*Intramuscular injections should be given to the anterior thigh.

†Young children with severe malaria have lower exposure to artesunate and its main biologically active metabolite dihydroartemisinin than do older children and adults. Revised dose regimens to ensure similar drug exposures have been suggested.

artemether-lumefantrine oral therapy. Oral and rectal administration of these artemisinin-based antimalarial drugs is effective in treatment of malaria, but such formulations are not indicated or approved in the United States.

Patients from areas with chloroquine-resistant *P. falciparum* who have mild infection, parasitemia less than 1%, no evidence of complications, and no vomiting and who can take oral medication can be considered for oral therapy with either oral atovaquone-proguanil (Malarone), oral artemether-lumefantrine (Coartem), or oral quinine plus doxycycline, tetracycline, or clindamycin (see **Table 288-2**). However, as noted in **Figure 288-5**, all children with clinical malaria, even those started on oral therapy, should be admitted to evaluate for progression of disease. Coartem is approved by the FDA for the treatment of uncomplicated malaria and is an appealing choice because it is highly effective and well-tolerated. Pediatric dosing is well established, but pediatric dispersible tablets, available in some other countries, are not yet available in the United States. Coartem should not be used in children with known QT interval prolongation. Patients who acquire *P. falciparum* in Thailand, Myanmar, or Cambodia should receive 7 days of quinine therapy if they are prescribed quinine. Mefloquine is contraindicated for use in patients with a known hypersensitivity to mefloquine or with a history of epilepsy or severe psychiatric disorders. Mefloquine is not recommended for persons with cardiac conduction abnormalities but may be administered to persons concurrently receiving β-blockers if they have no underlying arrhythmia. Quinidine or quinine may exacerbate the adverse effects of mefloquine and should generally not be given to patients who have received mefloquine unless there are no other alternatives.

Patients with uncomplicated *P. falciparum* malaria acquired in areas without chloroquine resistance should be treated with oral chloroquine phosphate. If the parasite count does not drop rapidly (within 24–48 hr) and become negative after 4 days, chloroquine resistance should be assumed and the patient started on a different antimalarial regimen.

Supportive therapy is very important and may include red blood cell transfusion(s) to maintain the hematocrit at more than 20%, exchange transfusion in *P. falciparum* malaria with parasitemia greater than 10% and evidence of severe complications (e.g., severe malarial anemia, cerebral malaria), supplemental oxygen and ventilatory support for pulmonary edema or cerebral malaria, careful intravenous rehydration for severe malaria, intravenous glucose for hypoglycemia, anticonvulsants for cerebral malaria with seizures, and dialysis for renal failure. Exchange transfusion is thought to be useful in severe malaria with high-level parasitemia, but no randomized clinical trial has ever been conducted to assess its utility, and some groups, including the Centers for Disease Control and Prevention, no longer advocate its use for severe malaria. Corticosteroids are not recommended for cerebral malaria.

**Plasmodium Vivax, P. Ovale, P. Malariae, or P. Knowlesi Malaria**

Uncomplicated infection caused by *P. vivax, P. ovale, or P. malariae* can usually be treated with chloroquine (see **Table 288-2**). Chloroquine remains the initial drug of choice for *P. vivax* malaria in the absence of good data on drug alternatives. Indications for using alternative therapy are worsening or new symptoms, persistent *P. vivax* parasitemia after 72 hr, and possibly acquisition of infection in Oceania or India. Patients with *P. vivax* or *P. ovale* malaria should also be given primaquine once daily for 14 days to prevent relapse from the hypnozoite forms that remain dormant in the liver. Some strains may require 2 courses of primaquine. Testing for glucose-6-phosphate dehydrogenase deficiency must be performed before initiation of primaquine, because it can cause hemolytic anemia in such patients. Unfortunately, no alternatives to primaquine currently exist for eradication of the hypnozoite forms of *P. vivax* or *P. ovale*. Patients with any type of malaria must be monitored for possible recrudescence with repeat blood smears at the end of therapy because recrudescence may occur more than 90 days after therapy with low-grade resistant organisms. If vomiting precludes oral administration, chloroquine can be given by nasogastric tube. Based on limited evidence, chloroquine plus sulfadoxine-pyrimethamine should be used to treat *P. knowlesi* infections. For cases of severe malaria caused by any *Plasmodium* species, intravenous quinidine or quinine along with a second drug (clindamycin, doxycycline, or tetracycline) should be used, as for *P. falciparum*. Patients with any type of malaria must be monitored for possible recrudescence with repeat blood smears at the end of therapy, because recrudescence may occur more than 90 days after therapy with low-grade resistant organisms. For children living in endemic areas, mothers should be encouraged to seek evaluation for malaria any time the child has a fever, as many clinics in endemic areas now have accurate rapid diagnostic tests available. If such children are severely ill, they should be given the same therapy as nonimmune children.
COMPLICATIONS OF PLASMODIUM FALCIPARUM MALARIA

The World Health Organization has identified 10 complications of *P. falciparum* malaria that define severe malaria (see Table 288-1 and Fig. 288-4). The most common complications in children are severe anemia, impaired consciousness (including cerebral malaria), respiratory distress (a result of metabolic acidosis), multiple seizures, prostration, and jaundice.

Severe malarial anemia (hemoglobin level <5 g/dL) is the most common severe complication of malaria in children and is the leading cause of anemia leading to hospital admission in African children. Anemia is associated with hemolysis, but removal of infected erythrocytes by the spleen and impairment of erythropoiesis likely play a greater role than hemolysis in the pathogenesis of severe malarial anemia. The primary treatment for severe malarial anemia is blood transfusion. With appropriate and timely treatment, severe malarial anemia usually has a relatively low mortality (~1%).

Cerebral malaria is defined as the presence of coma in a child with *P. falciparum* parasitemia and an absence of other reasons for coma. Children with altered mental status who are not in coma fall into the larger category of impaired consciousness. Cerebral malaria is most common in children in areas of midlevel transmission and in adolescents or adults in areas of very low transmission. It is less frequently seen in areas of very high transmission. Cerebral malaria often develops after the patient has been ill for several days but may develop precipitously. Cerebral malaria has a fatality rate of 15-20% and is associated with long-term cognitive impairment in children. Repeated seizures are frequent in children with cerebral malaria. Hypoglycemia is common, but children with true cerebral malaria fail to arouse from coma even after receiving a dextrose infusion that normalizes their glucose level. Physical findings may include high fever, seizures, muscular twitching, rhythmic movement of the head or extremities, contracted or unequal pupils, retinal hemorrhages, hemiplegia, absent or exaggerated deep tendon reflexes, and a positive Babinski sign. Lumbar puncture reveals increased pressure and cerebrospinal fluid protein with no pleocytosis and normal glucose and protein concentrations. Studies suggest that funduscopic findings of malaria retinopathy (retinal hemorrhages, peripheral whitening, macular whitening, vessel changes) are specific for cerebral malaria and may identify children in whom malaria is the reason for coma, as opposed to children with coma and incidental *P. falciparum* parasitemia. Treatment of cerebral malaria other than antimalarial medications is largely supportive and includes evaluation of and treatment of seizures and hypoglycemia. Although increased intracranial pressure has been documented in some children with cerebral malaria, treatment with mannitol and corticosteroids has not improved outcomes in these children.

Respiratory distress is a poor prognostic indicator in severe malaria and appears to be caused by metabolic acidosis rather than intrinsic pulmonary disease. To date, no successful interventions for treatment of metabolic acidosis in children with severe malaria have been described, but trials of dichloroacetate treatment and fluid expansion are ongoing.

Seizures are a common complication of severe malaria, particularly cerebral malaria. Benzodiazepines are first-line therapy for seizures, and intraartecal diazepam has been used successfully in children with malaria and seizures. Many seizures resolve with a single dose of diazepam. For persistent seizures, phenobarbital or phenytoin are the standard medications used. Phenytoin may be preferred for seizure treatment, particularly in hospitals or clinics where ventilatory support is not available. However, no comparative trials of the 2 drugs have been performed, and phenytoin is considerably more expensive than phenobarbital. There are currently no drugs recommended for seizure prophylaxis in children with severe malaria. Phenobarbital prophylaxis decreased seizure activity but increased mortality in 1 major study of children with severe malaria, probably because of the respiratory depression associated with phenobarbital that may have been exacerbated by benzodiazepine therapy.

Hypoglycemia is a complication of malaria that is more common in children, pregnant women, and patients receiving quinine therapy. Patients may have a decreased level of consciousness that can be confused with cerebral malaria. Any child with impaired consciousness and malaria should have a glucose level checked, and if glucometers are not available, an empirical bolus of dextrose should be given. Hypoglycemia is associated with increased mortality and neurologic sequelae.

Circulatory collapse (algid malaria) is a rare complication that manifests as hypotension, hypothermia, rapid weak pulse, shallow breathing, pallor, and vascular collapse. Death may occur within hours. Severe malaria is occasionally accompanied by bacteremia, which may have been the cause of some of the cases previously referred to as algid malaria. Any child with severe malaria and hypotension or hypoperfusion should have a blood culture obtained and be treated empirically for bacterial sepsis.

Long-term cognitive impairment occurs in 25% of children with cerebral malaria and also occurs in children with repeated episodes of uncomplicated disease. Prevention of attacks in these children improves educational attainment.

Tropical splenomegaly syndrome is a chronic complication of *P. falciparum* malaria in which massive splenomegaly persists after treatment of acute infection. The syndrome is characterized by marked splenomegaly, hepatomegaly, anemia, and an elevated immunoglobulin M level. Tropical splenomegaly syndrome is thought to be caused by an impaired immune response to *P. falciparum* antigens. Prolonged antimalarial prophylaxis (for at least several years) is required to treat this syndrome if the child remains in a malaria endemic area. Spleen size gradually regresses on antimalarial prophylaxis but often increases again if prophylaxis is stopped.

Other complications in children include jaundice, which is associated with a worse outcome, and prostration. Prostration is defined as the inability to sit, stand, or eat without support, in the absence of impaired consciousness. Prostration also has been associated with increased mortality in some studies, but the pathophysiology of this process is not well understood. Uncommon complications include hemoglobinuria, abnormal bleeding, pulmonary edema, and renal failure. These are uncommon complications in children with severe malaria and are more common in adults, particularly pulmonary edema and renal failure. Although frank renal failure is uncommon in children, uremia (when defined as an elevation in blood urea nitrogen levels) is not, particularly in older children. It remains unclear whether BUN elevation reflects a degree of renal failure or primarily dehydration.

PREVENTION

Malaria prevention consists of reducing exposure to infected mosquitoes and chemoprophylaxis. The most accurate and current information on areas in the world where malaria risk and drug resistance exist can be obtained by contacting local and state health departments or the CDC or consulting Health Information for International Travel, which is published by the U.S. Public Health Service.

Travelers to endemic areas should remain in well-screened areas from dusk to dawn, when the risk for transmission is highest. They should sleep under permethrin-treated mosquito netting and spray insecticides indoors at sundown. During the day the travelers should wear clothing that covers the arms and legs, with trousers tucked into shoes or boots. Mosquito repellent should be applied to thin clothing and exposed areas of the skin, with applications repeated every 1-2 hr. A child should not be taken outside from dusk to dawn, but if at risk for exposure, a solution with 25-35% N,N-diethyl-3-methylbenzamide (DEET) (not greater than 40%) should be applied to exposed areas except for the eyes, mouth, or hands. Hands are excluded because they are often placed in the mouth. DEET should then be washed off as soon as the child comes back inside. The American Academy of Pediatrics recommends that DEET solutions be avoided in children less than 2 mo of age. Adverse reactions to DEET include rashes, toxic encephalopathy, and seizures, but these reactions occur almost exclusively with inappropriate application of high concentrations of DEET. Picaridin is an alternative and sometimes better tolerated repellent. Even with these precautions, a child should be taken to a physician immediately if the child develops illness when traveling to a malarious area.
Chemoprophylaxis is necessary for all visitors to and residents of the tropics who have not lived there since infancy, including children of all ages (Table 288-5). Healthcare providers should consult the latest information on resistance patterns before prescribing prophylaxis for their patients. Chloroquine is given in the few remaining areas of the world free of chloroquine-resistant malaria strains. In areas where chloroquine-resistant *P. falciparum* exists, atovaquone-proguanil, mefloquine, or doxycycline may be given as chemoprophylaxis. Atovaquone-proguanil is generally recommended for shorter trips (up to 2 wk) because it must be taken daily. Pediatric tablets are available and are generally well tolerated, although the taste is sometimes unpleasant to very young children. For longer trips, mefloquine is preferred, as it is given only once a week. Mefloquine does not have a pediatric formulation and has an unpleasant taste that usually requires that the cut tablet be “disguised” in another food, such as chocolate syrup. Mefloquine should not be given to children if they have a known hypersensitivity to mefloquine, are receiving cardiotropic drugs, have a history of convulsive or certain psychiatric disorders, or travel to an area where mefloquine resistance exists (the borders of Thailand with Myanmar and Cambodia, the western provinces of Cambodia, and the eastern states of Myanmar). Atovaquone-proguanil is started 1-2 days before travel, and mefloquine is started 2 wk before travel. It is important that these doses are given, both to allow therapeutic levels of the drugs to be achieved and to be sure that the drugs are tolerated. Doxycycline is an alternative for children older than 8 yr of age. It must be given daily and should be given with food. Side effects of doxycycline include photosensitivity and vaginal yeast infections. Primaquine is a daily prophylaxis option for children who cannot tolerate any of the other options, but it should be provided in consultation with a travel medicine specialist if needed, and all children should be checked for glucose-6-phosphate dehydrogenase deficiency prior to prescribing this medication, which is contraindicated in children with glucose-6-phosphate dehydrogenase deficiency. Provision of medication can be considered in individuals who refuse to take prophylaxis or will be in very remote areas without accessible medical care. Provision of medication for self-treatment of malaria should be done in

*Chloroquine and mefloquine should be started 1-2 wk prior to departure and continued for 4 wk after last exposure.

*1Mefloquine resistance exists in western Cambodia and along the Thailand–Cambodia and Thailand–Myanmar borders. Travelers to these areas should take doxycycline or atovaquone-proguanil. See text for precautions about mefloquine use.

*2Doxycycline should be started 1-2 days prior to departure and continued for 4 wk after last exposure. Do not use in children younger than 8 yr of age or in pregnant women.

*3Atovaquone/proguanil (Malarone) should be started 1-2 days prior to departure and continued for 7 days after last exposure. Should be taken with food or a milky drink. Not recommended in pregnant women, children weighing <5 kg, and women breastfeeding infants who weigh <5 kg. Contraindicated in individuals with severe renal impairment (creatinine clearance <30 mL/min).

consultation with a travel medicine specialist, and the medication provided should be different than that used for prophylaxis.

A number of other efforts are currently underway to prevent malaria in malaria endemic countries. Some have been highly successful, leading to a significant decrease in malaria incidence in many countries in Africa, Asia, and South America in the last decade. These interventions include the use of insecticide-treated bed nets (which have decreased all-cause mortality in children under 5 yr of age in several highly malaria endemic areas by ~20%), indoor residual spraying with long-lasting insecticides, and the use of artemisinin-combination therapy for first-line malaria treatment. The first malaria vaccine to have any degree of efficacy is the RTS,S vaccine, which is based on the circumsporozoite protein of *P. falciparum*. In various clinical trials, this vaccine has shown an efficacy of 17-56% against uncomplicated malaria and 38-50% against severe malaria in young children in malaria endemic areas for periods as long as 48 mo after vaccination. The vaccine is in large phase III trials. Given the relatively low efficacy of this vaccine, it is unclear if it will be implemented as part of a combination strategy that includes the already successful interventions mentioned. Numerous other vaccines are also in current clinical trials, and it is hoped that future vaccines will improve upon the efficacy of the RTS,S vaccine. There is currently no vaccine with sufficient efficacy to be considered for prevention of malaria in travelers.

Intermittent prevention treatment during infancy has been particularly successful in reducing the incidence of malaria in sub Saharan Africa. Sulfadoxine-pyrimethamine given to infants at the second and third doses of the diphtheria, tetanus toxoid, and pertussis and measles vaccinations is safe and relatively effective. Intermittent prevention treatment has also been given to pregnant women; 3 doses of sulfadoxine-pyrimethamine have resulted in a reduction of low birth-weight infants.

Bibliography
Babesiosis is an emerging disease caused by intraerythrocytic protozoa that are transmitted by hard body (ixodid) ticks. The clinical manifestations of babesiosis range from subclinical illness to fulminating disease resulting in death.

**ETIOLOGY**

There are more than 100 species of Babesia that infect a wide variety of wild and domestic animals throughout the world. Only a few of these species have been reported to infect humans, including Babesia microti (and B. microti-like species), Babesia divergens (and B. divergens-like species), Babesia duncani, Babesia venatorum, and KO1.

**EPIDEMIOLOGY**

Babesia are transmitted to humans from vertebrate reservoir hosts by the Ixodes species of ticks. B. microti is the most common cause of babesiosis in humans. The primary reservoir for B. microti is the white-footed mouse, Peromyscus leucopus, and the primary vector is Ixodes scapularis, the black legged tick. I. scapularis ticks also transmit the causative agents of Lyme disease, human granulocytic anaplasmosis, Borrelia miyamotoi, and Powassan virus and may simultaneously transmit 2 or more microorganisms. White-tailed deer (Odocoileus virginianus) serve as the host on which adult ticks most abundantly feed but are incompetent reservoirs. Babesiosis may be transmitted through blood transfusion, and B. microti is the most frequently reported transfusion-transmitted microbial agent in the United States. Rarely, babesiosis is acquired by transplacental transmission.

Human B. microti infection is endemic (most cases occurring in June, July, and August) in the northeastern and upper midwestern United States and has been sporadically reported in China, Taiwan, and Europe (Fig. 289-1). Human babesial infections caused by the cattle parasite, B. divergens, have been described in many countries in Europe, while B. divergens-like infections have been described in Kentucky, Missouri, and Washington State. B. duncani infects humans along the northern Pacific coast. B. venatorum infects people in Austria, Germany, China, and Italy. Human babesiosis cases also have been documented in Africa, Australia, and South America.

In certain sites and in certain years of high transmission, babesiosis constitutes a significant public health burden. On Nantucket Island, case rates as high as 280 per 100,000 population have been recorded, placing the community burden of disease in a category with gonorrhea as “moderately common.” Comparable incidence rates have been described elsewhere on the southern New England coast.

**PATHOGENESIS**

The pathogenesis of human babesiosis is not well understood. Cytokine release and lysis of infected erythrocytes and excessive production of proinflammatory cytokines such as tumor necrosis factor and interleukin-1 may account for most of the clinical manifestations and complications of the disease. The spleen has an important role in clearing parasitemia as do T and B cells, macrophages, polymorphonuclear leukocytes, cytokines, antibody, and complement.

**CLINICAL MANIFESTATIONS**

The clinical severity of babesiosis ranges from subclinical infection to fulminating disease and death. In clinically apparent cases, symptoms of babesiosis begin after an incubation period of 1-4 wk from the beginning of tick feeding or 1 wk to 6 mo after transfusion. Typical symptoms in moderate to severe infection include intermittent fever to as high as 40.9°C (105.6°F) accompanied by any combination of fatigue, chills, sweats, myalgias, headache, and anorexia. Less commonly noted are emotional lability, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough. The findings on physical examination generally are minimal, often consisting only of fever. Splenomegaly, hepatomegaly, or both are noted occasionally, but rash seldom is reported. Abnormal laboratory findings include moderate to severe hemolytic anemia, elevated reticulocyte count, thrombocytopenia, proteinuria, and elevated bilirubin, blood urea nitrogen, and creatinine levels. The leukocyte count is normal to slightly decreased, with increased bands. Babesiosis symptoms usually last for 1 to 2 weeks, with prolonged recovery of up to a year or more in severe cases. Complications include respiratory failure, disseminated intravascular coagulation, congestive heart failure, renal failure, liver failure, and coma. A prolonged relapsing course of illness has been described in highly immunocompromised hosts, such as those with cancer, with asplenia, and on treatment with immunosuppressive agents, even though they received multiple courses of antibabesial therapy. About a quarter of these patients died, while the remainder were cured after an average of 3 mo (range: 1-24 mo) of antibabesial therapy.

**Risk factors for severe disease** include anatomic or functional asplenia, concomitant malignancy or HIV infection, immunosuppressive drugs, age of more than 50 yr, acquisition of infection through blood transfusion, or infection with B. divergens or B. duncani. Concurrent babesiosis and Lyme disease occurs in 3%-11% of patients experiencing Lyme disease depending upon location in southern New England and the northern Midwest. Such coinfection results in more severe acute Lyme disease illness. Moderate to severe babesiosis may occur in children, but infection generally is less severe than in adults. About half of infected children are asymptomatic or experience minimal symptoms. Neonates may develop severe illness and usually are infected from blood transfusion.
The diagnosis of babesiosis should be considered in any patient with an unexplained febrile illness who has resided in or traveled to an endemic area within the previous 2 mo or received a blood transfusion within the previous 6 mo. The diagnosis is confirmed by microscopic identification of parasites on blood smear or amplifiable Babesia DNA in blood and antibacteral antibody in serum. Babesia are identified on blood smear using Giemsa or Wright staining. Parasitemia may be exceedingly low, especially early in the course of illness. Thick blood smears may be examined, but the organisms may be mistaken for stain precipitate or iron inclusion bodies. The polymerase chain reaction is a sensitive and specific test for detection of Babesia DNA. Subinoculation of blood into hamsters or gerbils and in vitro cultivation are too specialized for all but the most experienced laboratories. Serologic testing is useful, particularly for diagnosing B. microti infection. The indirect immunofluorescence serologic assay for both immunoglobulin G and immunoglobulin M antibodies is sensitive and specific and can help confirm a diagnosis of babesiosis when parasites are scarce or undetectable. The diagnosis of active babesial infection based on seropositivity alone is unreliable.

The combination of clindamycin (7-10 mg/kg given every 6-8 hr [up to a maximum of 600 mg per dose] intravenously or orally) and quinine (8 mg/kg given every 8 hr [up to a maximum of 650 mg per dose] orally) for 7-10 days was the first effective therapeutic combination for the treatment of babesiosis and remains the treatment of choice for severe disease. Adverse reactions are common, however, especially tinnitus and abdominal distress. The combination of atovaquone (20 mg/kg every 12 hr [up to a maximum of 750 mg per dose]) and azithromycin (10 mg/kg per day once per day on day 1 [up to a maximum of 500 mg per dose] and 5 mg/kg once per day [up to a maximum of 250 mg per dose] thereafter orally) for 7-10 days is as effective as clindamycin and quinine but has fewer adverse effects. Combination atovaquone and azithromycin has been used successfully to treat babesiosis in infants and should be considered for initial use in children experiencing mild to moderate infection. Treatment failure with clindamycin and quinine and with atovaquone and azithromycin may occur in highly immunocompromised hosts. Consultation with an infectious diseases expert is recommended in these cases. Exchange blood transfusion can decrease parasitemia rapidly and remove toxic by-products of infection. It should be considered for all patients experiencing severe babesiosis.

Moderate to severe disease is frequently observed in some highly endemic areas. The case fatality rate was estimated at 5% in a retrospective study of 136 New York cases but may be as high as 21% in immunocompromised hosts. Immunity is sometimes incomplete with low-level asymptomatic parasitemia persisting for as long as 26 mo after symptoms have resolved or with relapsing symptomatic disease in immunocompromised hosts.

Prevention of babesiosis can be accomplished by avoiding areas where ticks, deer, and mice are known to thrive. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide (DEET), dimethyl phthalate, or permethrin (Permanone) is recommended for those who travel in the foliage of endemic areas. A search for ticks on people and pets should be carried out and the ticks removed using tweezers. Prospective blood donors with a history of babesiosis are excluded from giving blood to prevent transfusion-related cases.

Bibliography
Toxoplasmosis, an obligate intracellular protozoan, is acquired perorally, transplacentally, or, rarely, parenterally in laboratory accidents; by transfusion; or from a transplanted organ. In immunologically normal children, acute acquired infection may be asymptomatic, cause lymphadenopathy, or affect almost any organ. Once acquired, latent encysted organisms persist in the host throughout life. In immunocompromised persons either initial acquisition or recrudescence of latent organisms often causes signs or symptoms related to the central nervous system (CNS) and can result in systemic disease in bone marrow transplant recipients. If untreated, congenital infection often causes disease either perinatally or later in life, most frequently chorioretinitis and CNS lesions. Other manifestations, such as intrauterine growth retardation, prematurity, being small for gestational age, cognitive and motor deficits, fever, lymphadenopathy, rash, hearing loss, pneumonitis, hepatitis, thrombocytopenia, and cerebrospinal fluid (CSF) inflammatory changes such as pleocytosis, elevated CSF protein, and low CSF glucose, may also occur. Congenital toxoplasmosis in infants with HIV infection may be fulminant.

**ETIOLOGY**

*Toxoplasma gondii* is a coccidian protozoan that multiplies only in living cells. The tachyzoites are oval or crescent-like, measuring 2-4 × 4-7 μm. Tissue cysts, which are 10-100 μm in diameter, may contain thousands of parasites, and will remain in tissues, especially the CNS and skeletal and heart muscle, for the life of the host. *Toxoplasma* can multiply in all tissues of mammals and birds.

Newly infected cats and other Felidae species excrete infectious *Toxoplasma* oocysts in their feces. *Toxoplasma* organisms are transmitted to cats by ingestion of infected meat containing encysted bradyzoites or by ingestion of oocysts excreted by other recently infected cats. The parasites then multiply through schizontogenic and gametogenic cycles in the distal ileal epithelium of the cat intestine. Oocysts containing 2 sporocysts are excreted, and, under proper conditions of temperature and moisture, each sporocyst matures into 4 sporozoites. For approximately 2 wk the cat excretes 10⁵-10⁸ oocysts/day, which may remain their viability for longer than 1 yr in a suitable environment. Oocysts sporulate 1-5 days after excretion and are then infectious. Oocysts are killed by drying or boiling but not exposure to bleach. Oocysts have been isolated from soil and sand frequented by cats, and outbreaks associated with contaminated food and water have been reported. Oocysts and tissue cysts are sources of animal and human infections (Fig. 290-1). There are genetically distinct types of *T. gondii* that have different virulence for mice (and perhaps for humans) and form different numbers of cysts in the brains of outbred mice. In the United States, there are 4 predominant clonal lineages called types I, II, III, and IV (haplogroup XII) in addition to atypical, recombinant types. Virulence differs based on parasite genetics. There is 1 predominant clonal type in France, Austria, and Poland, and nonarchetypal parasites in Brazil, Guyana, French Guiana, and Central America.

**EPIDEMIOLOGY**

*Toxoplasma* infection is ubiquitous in animals and is one of the most common latent infections of humans throughout the world. Incidence varies considerably among people and animals in different geographic areas. In many areas of the world, approximately 3-35% of pork, 7-60% of lamb, and 0-9% of beef contain *T. gondii* organisms. Significant antibody titers are detected in 50-80% of residents of some localities, such as France, Brazil, and Central America, and in <5% in other areas. There is a higher prevalence of infection in warmer, more humid climates. Non-II genetic type parasites are more common in mothers of congenitally infected infants in warm, moist southern climates, in rural areas with lower socioeconomic status, and in places with Hispanic ethnicity in the United States.

Human infection is usually acquired orally by eating undercooked or raw meat that contains cysts or food or other material contaminated with oocysts from acutely infected cats. Freezing meat to −20°C (−4°F) or heating meat to 66°C (150.8°F) renders the cysts noninfectious. Outbreaks of acute acquired infection have occurred in families, at social gatherings, and in restaurants where people have consumed the same infected food. *Toxoplasma* organisms are not known to be transmitted from person to person except for transplacental infection from mother to fetus and, rarely, by organ transplantation or transfusion. Seronegative transplant recipients who receive an organ or bone marrow from seropositive donors have experienced life-threatening illness requiring therapy. Seropositive recipients may have increased serologic titers without associated disease. Laboratory accidents have resulted in infections, including fatalities.

**Congenital Toxoplasmosis**

Transmission to the fetus usually follows acquisition of primary infection by an immunologically normal pregnant woman during gestation. Congenital transmission from mothers infected before pregnancy is extremely rare except for immunocompromised women who are chronically infected. The incidence of congenital infection in the United States ranges from 1 in 1,000 to 1 in 8,000 live births. The incidence of infection among pregnant women depends on the general risk for infection in the specific locale and the proportion of the population that has not been infected previously.

**PATHOGENESIS**

*Toxoplasma gondii* is acquired by children and adults from ingesting food that contains cysts or that is contaminated with oocysts from acutely infected cats. Oocysts also may be transported to food by flies and cockroaches or be carried on the fur of dogs. When the organism is ingested, bradyzoites are released from cysts or sporozoites from oocysts. The organisms enter gastrointestinal cells where they multiply, rupture cells, infect contiguous cells, enter the lymphatics, and disseminate hematogenously throughout the body. Tachyzoites proliferate, producing necrotic foci surrounded by a cellular reaction. With development of a normal immune response that is both humoral and cell mediated, tachyzoites disappear from tissues. In immunocompromised persons and also some apparently immunocompetent persons, acute infection progresses and may cause potentially lethal disease, including pneumonitis, myocarditis, or encephalitis.

Alterations of T-lymphocyte populations during acute *T. gondii* infection are common and include lymphocytosis, increased CD8 count, and decreased CD4:CD8 ratio. Depletion of CD4 cells in patients with AIDS may contribute to severe manifestations of toxoplasmosis. Characteristic lymph node changes include reactive follicular hyperplasia with irregular clusters of epithelioid histiocytes that encroach on and blur margins of germinal centers, and focal distortion of sinuses with monocytoid cells.

Cysts form as early as 7 days after infection and remain for the life of the host. During latent infection they produce little or no inflammatory response and may cause recrudescent disease in immunocompromised persons. Recrudescent chorioretinitis occurs in children with postnatal infection and in older children and adults with congenital infection. Host and parasite genetics influence outcome.

**Congenital Toxoplasmosis**

When a mother acquires infection during gestation, organisms may disseminate hematogenously to the placenta. Infection may be transmitted to the fetus transplacentally or during vaginal delivery. Of
Infectious Diseases appear to have Toxoplasma antigen-specific cell-mediated anergy, which may be important in the pathogenesis of disease.

CLINICAL MANIFESTATIONS

Manifestations of primary infection with T. gondii are highly variable and are influenced primarily by host immunocompetence. There may be no signs or symptoms or severe disease. Reactivation of previously asymptomatic congenital toxoplasmosis usually manifests as ocular toxoplasmosis.

Acquired Toxoplasmosis

Immunocompetent children who acquire infection postnatally generally do not have clinically recognizable symptoms. When clinical manifestations are apparent, they may include almost any combination of fever, stiff neck, myalgia, arthralgia, maculopapular rash that spares the palms and soles, localized or generalized lymphadenopathy, hepatomegaly, hepatitis, reactive lymphocytosis, meningitis, brain abscess, encephalitis, confusion, malaise, pneumonia, polymyositis, pericarditis, pericardial effusion, and myocarditis. Chorioretinitis is usually untreated maternal infections acquired in the 1st trimester, approximately 17% of fetuses are infected, usually with severe disease. Of untreated maternal infection acquired in the 3rd trimester, approximately 65% of fetuses are infected, usually with disease that is more mild or inapparent at birth. These different rates of transmission and outcomes are most likely related to placental blood flow, virulence, inoculum of T. gondii, and immunologic capacity of the mother and fetus to limit parasitemia.

Examination of the placenta of infected newborns may reveal chronic inflammation and cysts. Tachyzoites can be seen with Wright or Giemsa stains but are best demonstrated with immunoperoxidase technique. Tissue cysts stain well with periodic acid–Schiff and silver stains as well as with the immunoperoxidase technique. Gross or microscopic areas of necrosis may be present in many tissues, especially the CNS, choroid and retina, heart, lungs, skeletal muscle, liver, and spleen. Areas of calcification occur in the brain.

Almost all congenitally infected individuals who are not treated manifest signs or symptoms of infection, such as chorioretinitis, by adolescence. Some severely involved infants with congenital infection appear to have Toxoplasma antigen-specific cell-mediated anergy, which may be important in the pathogenesis of disease.

Figure 290-1 Life cycle of Toxoplasma gondii and prevention of toxoplasmosis by interruption of transmission to humans.
unilateral and is estimated to occur in approximately 1% of cases in the United States. Approximately 10% of mothers of congenitally infected infants also have eye lesions. Acquired chorioretinal lesions cannot be distinguished from congenital infection based on their appearance. In some areas of Brazil, 80% of the population is infected and, of these, 20% have retinal involvement. Ocular symptoms may be present for a few days only or may persist for many months. The most common manifestation of acute acquired toxoplasmosis is enlargement of 1 or a few cervical lymph nodes. Cases of Toxoplasma lymphadenopathy can resemble infectious mononucleosis, lymphoma, or other lymphadenopathies (see Chapter 490). In the pectoral area in older girls and women, enlarged nodes may be confused with breast neoplasms. Mediastinal, mesenteric, and retroperitoneal lymph nodes may be involved. Involvement of intraabdominal lymph nodes may be associated with fever, mimicking appendicitis. Nodes may be tender but do not suppurate. Lymphadenopathy may wax and wane for as long as 1-2 yr. However, almost all patients with lymphadenopathy recover spontaneously without antimicrobial therapy. Significant organ involvement in immunologically normal persons is uncommon, although some individuals have suffered significant morbidity, including rare cases of encephalitis, brain abscesses, hepatitis, myocarditis, pericarditis, and polymyositis. In persons acquiring T. gondii in Guyana and along Amazon tributaries, a severe form of multivisceral involvement with fever has occurred.

**Ocular Toxoplasmosis**

In the United States and Western Europe, T. gondii is estimated to cause 35% of cases of chorioretinitis (Fig. 290-2). In Brazil, T. gondii retinal lesions are common. Clinical manifestations include blurred vision, visual floaters, photophobia, epiphora, and, with macular involvement, loss of central vision. Ocular findings of congenital toxoplasmosis also include strabismus, microphthalmia, microcornea, cataracts, anisometropia, nystagmus, glaucoma, optic neuritis, and optic atrophy. Episodic recurrences are common, but precipitating factors have not been defined. Recurrent, active disease occurs most commonly at school-entry age and during adolescence. Anecdotally, stress or trauma seems to precipitate symptoms. Recurrences are most common closest to the time of acquisition of infection, and treatment leads to resolution of activity.

**Immunocompromised Persons**

Disseminated T. gondii infection among older children who are immunocompromised by AIDS, malignancy, cytotoxic therapy, corticosteroids, or immunosuppressive drugs given for organ transplantation involves the CNS in 50% of cases and may also involve the heart, lungs, and gastrointestinal tract. Stem cell transplant recipients present a special problem, because active infection is difficult to diagnose serologically. After transplantation, T. gondii-specific antibody levels may remain the same, increase, or decrease, and can even become undetectable. Toxoplasmosis in transplantation patients almost always results from transplantation from a seropositive donor to a seronegative recipient. Active infection is often fulminant and rapidly fatal without treatment.

Congenital T. gondii infection in infants with HIV infection is rare and can be a severe and fulminant disease with substantial CNS involvement. Alternatively, it may be more indolent in presentation, with focal neurologic deficits or systemic manifestations such as pneumonitis occurring with CD4 depletion.

Figure 290-2 Toxoplasmic chorioretinitis. A, Retinal photographs of a child with severe vitreitis that is less intense than the classic “headlight in fog” appearance (left). Resolving vitreitis caused by underlying active lesion (middle). Resolved healed lesion without vitreitis (right). B, Retina photographs for a newborn infant with active vitreitis (left, labeled “near birth”) with clearing of vitreitis and marked, but not complete, resolution of activity of the lesion 3 wk later (right, labeled “with ongoing treatment”). C, Retinal photographs of a child showing an active lesion at presentation (left), and scarred lesion (right). D, Retinal photographs showing an active retinal lesion before treatment (left) and a completely resolved normal appearing retina within 1 mo of initiating treatment (right). E, Example of active choroidal neovascular membranes (CNVMs) in a child. Fundus photographs (top row), fluorescein angiogram (FA; middle row), and ocular coherence tomography (OCT; bottom row) of a child at presentation (first column), 7 wk after first ranibizumab (Lucentis, antibody to VEGF) injection (second column), and 11 wk after first ranibizumab injection (third column). (A to D adapted from Delair E, Latkany P, Noble AG, et al: Clinical manifestations of ocular toxoplasmosis, Ocul Immunol Inflamm 19:91–102, 2011; E adapted from Benevento JD, Jager RD, Noble AG, et al: Toxoplasmosis-associated neovascular lesions treated successfully with ranibizumab and antiparasitic therapy, Arch Ophthalmol 126:1152–1156, 2008.)
From 25-50% of persons with *T. gondii* antibodies and HIV infection without antiretroviral treatment eventually experience toxoplasmonic encephalitis, which is fatal if not treated. Highly active antiretroviral therapy and trimethoprim-sulfamethoxazole prophylaxis have diminished the incidence of toxoplasmosis in patients with HIV infection, but toxoplasmonic encephalitis remains a presenting manifestation in adult patients with AIDS. Typical findings include fever, headache, altered mental status, psychosis, cognitive impairment, seizures, and focal neurologic defects, including hemiparesis, aphasia, ataxia, visual field loss, cranial nerve palsies, and dysmetria or movement disorders. In adult patients with AIDS, toxoplasmonic retinal lesions are often large with diffuse necrosis and contain many organisms but little inflammatory cellular infiltrate. Diagnosis of presumptive toxoplasmonic encephalitis based on neuroradiologic studies in patients with AIDS necessitates a prompt therapeutic trial of medications effective against *T. gondii*. Clear clinical improvement within 7-14 days and improvement of neuroradiologic findings within 3 wk makes the presumptive diagnosis almost certain.

**Congenital Toxoplasmosis**

Congenital toxoplasmosis usually occurs when a woman acquires primary infection while pregnant. Most often, maternal infection is asymptomatic or without specific symptoms or signs. As with other adults with acute toxoplasmosis, lymphadenopathy is the most common symptom. In monozygotic twins the clinical pattern of involvement is most often similar, whereas in dizygotic twins the manifestations often differ, including cases of congenital infection in only 1 twin. The major histocompatibility complex class II gene DQ3 appears to be more frequent among HIV-infected persons seropositive for *T. gondii* who develop toxoplasmonic encephalitis, and in children with congenital toxoplasmosis who develop hydrocephalus. These findings suggest that the presence of HLA-DQ3 is a risk factor for severity of toxoplasmosis. Other allelic variants of genes, including COL2A, ABC4R, P2X7R, NALP1, TLR9, and ERAAP, are also associated with susceptibility.

Congenital infection may present as a mild or severe neonatal disease. It may also present with sequelae or relapse of a previously undiagnosed and untreated infection later in infancy or even later in life. There is a wide variety of manifestations of congenital infection, ranging from hydrops fetalis and perinatal death to small size for gestational age, prematurity, peripheral retinal scars, persistent jaundice, mild thrombocytopenia, CSF pleocytosis, and the characteristic triad of chorioretinitis, hydrocephalus, and cerebral calcifications. More than 50% of congenitally infected infants are considered normal in the perinatal period, but almost all such children develop ocular involvement later in life if they are not treated during infancy. Neurologic signs such as convulsions, setting-sun sign with downward gaze, and hydrocephalus with increased head circumference may be associated with substantial cerebral damage or with relatively mild inflammation obstructing the aqueduct of Sylvius. If affected infants are treated and shunted promptly, signs and symptoms may resolve and development may be normal.

The spectrum and frequency of neonatal manifestations of 210 newborns with congenital Toxoplasma infection identified by a serologic screening program of pregnant women were described in 1984. In this study, 10% had severe congenital toxoplasmosis with CNS involvement, eye lesions, and general systemic manifestations; 34% had mild involvement with normal clinical examination results other than retinal scars or isolated intracranial calcifications; and 55% had no detectable manifestations. These numbers represent an underestimate of the incidence of severe congenital infection for several reasons: the most-severe cases, including most of those individuals who died, were not referred; therapeutic abortion sometimes was performed when acute acquired infection of the mother was diagnosed early during pregnancy; in utero spiramycin therapy prevented or diminished the severity of infection; only 13 of the 210 congenitally infected newborns had brain CT, and only 77% of these 210 infants had a CSF examination. Routine newborn examinations often yield normal findings for congenitally infected infants, but more careful evaluations may reveal significant abnormalities. In a 2012 analysis of the National Collaborative Chicago-Based Congenital Toxoplasmosis Study (NCCCTS) (1981-2009) data, it was found that 72% of children at or near birth had chorioretinal scars, 70% had CNS calcifications, 12% had microcephalus, 37% had hydrocephalus, 41% had thrombocytopenia, 39% had hepatomegaly, 32% had splenomegaly, and 41% were born prematurely (Fig. 290-3). In 1 study of 28 infants identified by a universal state-mandated serologic screening program for *T. gondii*–specific immunoglobulin (Ig) M, 26 had normal findings on routine newborn examination but 14 had significant abnormalities detected with more careful evaluation. The abnormalities included retinal scars (7 infants), active chorioretinitis (3 infants), and CNS abnormalities (8 infants). In Fiocruz, Belo Horizonte, Brazil, infection is common, occurring in 1 in 600 live births. Half of these infected infants have active chorioretinitis at birth. When the infection is acquired in utero and the fetus is treated by treatment of the pregnant woman with pyrimethamine, sulfadiazine, and leucovorin, signs and symptoms in the infant may be prevented. The newborn infant may appear normal with no CSF abnormalities and no brain or eye disease. In utero treatment initiated rapidly results in a reduction of ocular and neurologic sequelae.

There is also a wide spectrum of symptoms of untreated congenital toxoplasmosis that presents later in the 1st yr of life (Table 290-1). More than 80% of these children have IQ scores of <70, and many have convulsions and severely impaired vision.

**SYSTEMIC SIGNS**

From 25% to >50% of infants with clinically apparent disease at birth are born prematurely. Parasite clonal types other than type II are more often associated with prematurity and more-severe disease. Intrauterine growth retardation, low Apgar scores, and temperature instability are common. Other manifestations may include lymphadenopathy, hepatosplenomegaly, myocarditis, pneumonitis, nephrotic syndrome, vomiting, diarrhea, and feeding problems. Bands of metaphyseal lucency and irregularity of the line of provisional calcification at the epiphyseal plate may occur without periosteal reaction in the ribs, femurs, and vertebrae. Congenital toxoplasmosis may be confused with erythroblastosis fetalis resulting from isosensitization, although
Endocrine Abnormalities

Endocrine abnormalities may occur secondary to hypothalamic or pituitary involvement or end-organ involvement but are not common. Occasionally reported endocrinopathies include myxedema, persistent hypernatremia with vasopressin-sensitive diabetes insipidus, sexual precocity, and partial anterior hypopituitarism.

Central Nervous System

Neurologic manifestations of congenital toxoplasmosis vary from massive acute encephalopathy to subtle neurologic syndromes. Toxoplasmosis should be considered as a potential cause of any undiagnosed neurologic disease in children younger than 1 yr of age, especially if retinal lesions are present.

Hydrocephalus may be the sole clinical neurologic manifestation of congenital toxoplasmosis and almost always requires shunt placement. Hydrocephalus may present prenatally and progress during the perinatal period, or, much less commonly, may present later in life. Patterns of seizures are protein and have included focal motor seizures, petit and grand mal seizures, muscular twitching, opisthotonus, and hypsarrhythmia. Spinal or bulbar involvement may be manifested by paralysis of the extremities, difficulty swallowing, and respiratory distress. Microcephaly usually reflects severe brain damage, but some children with microcephaly caused by congenital toxoplasmosis who have been treated have normal or superior cognitive function. Untreated congenital toxoplasmosis that is symptomatic in the 1st yr of life can cause substantial diminution in cognitive function and developmental delay. Intellectual impairment also occurs in some children with subclinical infection without or despite treatment with pyrimethamine and sulfonamides. Seizures and focal motor defects may become apparent after the newborn period, even when infection is subclinical at birth.

CSF abnormalities occur in at least 50% of infants with congenital toxoplasmosis. A CSF protein level of $>1$ g/dl is characteristic of severe CNS toxoplasmosis and is usually accompanied by hydrocephalus. Local production of T. gondii-specific IgG and IgM antibodies may be demonstrated. CT of the brain is useful to detect calcifications, determine ventricular size, and demonstrate porencephalic cystic structures (Fig. 290-4). Calcifications occur throughout the brain, but there is a propensity for development of calcifications in the caudate nucleus and basal ganglia, choroid plexus, and subependyma. MRI and contrast-enhanced CT brain scans are useful for detecting active inflammatory lesions. MRIs that take only a brief time ($<45$ sec) for imaging or ultrasonography may be useful for following ventricular size. Treatment in utero and in the 1st yr of life results in improved neurologic outcomes.

Eyes

Almost all untreated congenitally infected infants develop chorioretinal lesions by adulthood, and may have severe visual impairment. T. gondii causes a focal necrotizing retinitis in congenitally infected individuals (see Fig. 290-2). Retinal detachment may occur. Any part of the retina may be involved, either unilaterally or bilaterally, including the maculae. The optic nerve may be involved, and toxoplasmic lesions that involve projections of the visual pathways in the brain or the visual cortex also may lead to visual impairment. In association with severe retinal lesions and vitreitis, secondary anterior uveitis may develop and occasionally lead to erythema of the external eye. Other ocular findings include cells and protein in the anterior chamber, large keratic precipitates, posterior synechiae, nodules on the iris, and neovascular formation on the surface of the iris, sometimes with increased intraocular pressure and glaucoma. Rarely, the extraocular musculature may also be involved directly. Other manifestations include strabismus, nystagmus, visual impairment, and microphthalmia. Enucleation has been required for a blind, phthisic, painful eye. The differential diagnosis of ocular toxoplasmosis includes congenital coloboma and inflammatory lesions caused by cytomegalovirus, Treponema pallidum, Mycobacterium tuberculosis, or vasculitis. Ocular toxoplasmosis may be a recurrent and progressive disease that requires multiple courses of therapy.
Limited data suggest that occurrence of lesions in the early years of life may be prevented by instituting antimicrobial treatment with pyrimethamine and sulfonamides during the 1st yr of life and that treatment of the infected fetus in utero followed by treatment in the 1st yr of life with pyrimethamine, sulfadiazine, and leucovorin reduces the incidence and the severity of the retinal disease.

**Ears**
Sensorineural hearing loss, both mild and severe, may occur. It is not known whether this is a static or progressive disorder. Treatment in the 1st yr of life is associated with decreased frequency of hearing loss.

**DIAGNOSIS**
Diagnosis of acute *Toxoplasma* infection can be established by a number of methods (Table 290-2). For example, isolation of *T. gondii* from blood or body fluids; identification of tachyzoites in sections or preparations of tissues and body fluids, amniotic fluid, or placenta; identification of cysts in the placenta or tissues of a fetus or newborn; and characteristic lymph node histologic features establish the diagnosis. Serologic tests are very useful for diagnosis. Polymerase chain reaction (PCR) is useful to identify *T. gondii* DNA in CSF and amniotic fluid, and has been reported to be useful with infant peripheral blood and urine to definitively establish the diagnosis.

**Isolation**
Organisms are isolated by inoculation of body fluids, leukocytes, or tissue specimens into mice or tissue cultures. Body fluids should be processed and inoculated immediately, but *T. gondii* has been isolated from tissues and blood that have been stored overnight or even for 4-5 days at 4°C (39.2°F). Freezing or treatment of specimens with formalin kills *T. gondii*. From 6-10 days after inoculation into mice, or earlier if mice die, peritoneal fluids should be examined for tachyzoites. If inoculated mice survive for 6 wk and seroconvert, definitive diagnosis is made by visualization of *Toxoplasma* cysts in mouse brain. If cysts are not seen, subinoculations of mouse tissue into other mice are performed.

Microscopic examination of tissue culture inoculated with *T. gondii* shows necrotic, heavily infected cells with numerous extracellular tachyzoites. Isolation of *T. gondii* from blood or body fluids reflects acute infection. Except in the fetus or neonate, it is usually not possible to distinguish acute from past infection by isolation of *T. gondii* from tissues such as skeletal muscle, lung, brain, or eye obtained by biopsy or at autopsy.

Diagnosis of acute infection can be established by visualization of tachyzoites in biopsy tissue sections, bone marrow aspirate, or body fluids such as CSF or amniotic fluid. Immunofluorescent antibody and immunoperoxidase staining techniques may be necessary, because it is often difficult to distinguish the tachyzoite using ordinary stains. Tissue cysts are diagnostic of infection but do not differentiate between acute and chronic infection, although the presence of many cysts suggests recent acute infection. Cysts in the placenta or tissues of the newborn infant establish the diagnosis of congenital infection. Characteristic histologic features strongly suggest the diagnosis of toxoplasmic lymphadenitis.

**Serologic Testing**
Serologic tests are useful in establishing the diagnosis of congenital or acutely acquired *Toxoplasma* infection. Each laboratory that reports serologic test results must have established values for their tests that diagnose infection in specific clinical settings, provide interpretation of their results, and ensure appropriate quality control before therapy is based on serologic test results. Serologic test results used as the basis for therapy should be confirmed in a reference laboratory.

The *Sabin-Feldman dye test* is sensitive and specific. It measures primarily IgG antibodies. Results should be expressed in international units (IU/mL), based on international standard reference sera available from the World Health Organization. The IgG indirect fluorescent-antibody (IgG-IFA) test measures the same antibodies as the dye test, and the titers tend to be parallel. These antibodies usually appear 1-2 wk after infection, reach high titers (≥1:1,000) after 6-8 wk, and then decline over months to years. Low titers (1:4 to 1:64) usually persist for life. Antibody titer does not correlate with severity of illness.

An agglutination test (Bio-Mérieux, Lyon, France) that is available commercially in Europe uses formalin-preserved whole parasites to detect IgG antibodies. This test is accurate, simple to perform, and inexpensive.

The IgM-IFA test is useful for the diagnosis of acute acquired infection with *T. gondii* in the older child because IgM antibodies appear earlier, often by 5 days after infection, and diminish more quickly than IgG antibodies. In most instances, IgM antibodies rise rapidly (1:50 to <1:1,000) and then fall to low titers (1:10 or 1:20) or disappear after weeks or months. However, some patients continue to have positive IgM results with low titers for several years. The IgM-IFA test detects *Toxoplasma*-specific IgM in only approximately 25% of congenitally infected infants at birth. IgM antibodies may not be present in sera of infants at birth. IgM antibodies may not be present in sera of infants at birth.
immunocompromised patients with acute toxoplasmosis or in patients with reactivation of ocular toxoplasmosis. The IgM-IFA test may yield false-negative results as a result of rheumatoid factor.

The double-sandwich IgM enzyme-linked immunoabsorbent assay (IgM-ELISA) is also useful for detection of Toxoplasma IgM antibodies. In the older child, serum IgM-ELISA Toxoplasma antibodies of >2 (a value of 1 reference laboratory; each laboratory must establish its own value for positive results) indicates that Toxoplasma infection most likely has been acquired recently. The IgM-ELISA identifies approximately 50-75% of infants with congenital infection. IgM-ELISA avoids both the false-positive results from rheumatoid factor and the false-negative results from high levels of passively transferred maternal...
IgG antibody in fetal serum, as may occur in the IgM-IFA test. Results obtained with commercial kits must be interpreted with caution, because false-positive reactions are not infrequent. Care must also be taken to determine whether kits have been standardized for diagnosis of infection in specific clinical settings, such as in the newborn infant. The IgA-ELISA also is a sensitive test for detection of maternal and congenital infection, and results may be positive when those of the IgM-ELISA are not.

The immunosorbent agglutination assay (ISAGA) combines trapping of a patient’s IgM to a solid surface and use of formalin-fixed organisms or antigen-coated latex particles. It is read as an agglutination test. There are no false-positive results from rheumatoid factor or antinuclear antibodies. The IgM-ISAGA is more sensitive than the IgM-ELISA and may detect specific IgM antibodies before and for longer periods than the IgM-ELISA.

At present, the IgM-ISAGA and the IgA-ELISA are the most useful tests for diagnosis of congenital infection in the newborn. The IgE-ELISA and IgE-ISAGA are also sometimes useful in establishing the diagnosis of congenital toxoplasmosis or acute acquired T. gondii infection. The presence of IgM antibodies in the older child or adult can never be used alone to diagnose acute acquired infection.

The differential agglutination test (HS/AC) compares antibody titers obtained with formalin-fixed tachyzoites (HS antigen) with titers obtained using acetone- or methanol-fixed tachyzoites (AC antigen) to differentiate recent and remote infections in adults and older children. This method may be particularly useful in differentiating remote infection in pregnant women, because levels of IgM and IgA antibodies detectable by ELISA or ISAGA may remain elevated for months to years in adults and older children.

The avidity test can be helpful to establish time of acquisition of infection. A high-avidity test result indicates that infection began more than 12-16 wk earlier, which is especially useful in determining time of acquisition of infection in the 1st or final 16 wk of gestation. A low-avidity test result may be present for many months and is not diagnostic of recent acquisition of infection.

A relatively higher level of Toxoplasma antibody in the aqueous humor or in CSF demonstrates local production of antibody during active ocular or CNS toxoplasmosis. This comparison is performed, and a coefficient \([C]\) is calculated as follows:

\[ C = \frac{\text{Antibody titer in body fluid}}{\text{Antibody titer in serum}} \times \frac{\text{Concentration of IgG in serum}}{\text{Concentration of IgG in body fluid}} \]

Significant coefficients \([C]\) are >8 for ocular infection, >4 for CNS for congenital infection, and >1 for CNS in patients with AIDS. If the serum dye test titer is >300 IU/mL, it is not possible to demonstrate significant local antibody production using this formula with either the dye test or the IgM-IFA test titer. IgM antibody may be detectable in CSF.

Comparative Western immunoblot tests of sera from a mother and infant may detect congenital infection. Infection is suspected when the mother’s serum and her infant’s serum contain antibodies that react with different Toxoplasma antigens.

The enzyme-linked immunofiltration assay using micropore membranes permits simultaneous study of antibody specificity by immunoprecipitation and characterization of antibody isotypes by immunofiltration with enzyme-labeled antibodies. This method is capable of detecting 85% of cases of congenital infection in the 1st few days of life.

PCR is used to amplify the DNA of T. gondii, which then can be detected by using a DNA probe. Detection of repetitive T. gondii genes, the B1 or 529 bp, 300 copy gene, in amniotic fluid is the PCR target of choice for establishing the diagnosis of congenital Toxoplasma infection in the fetus. Sensitivity and specificity of this test in amniotic fluid obtained to diagnose infections acquired between 17 and 21 wk of gestation are approximately 95%. Before and after that time, PCR with the 529 bp, 300 copy repeat gene as the template is 92% sensitive and 100% specific for detection of congenital infection. PCR of vitreous or aqueous fluids also has been used to diagnose ocular toxoplasmosis. PCR of peripheral white blood cells, CSF, and urine has been reported to detect congenital infection.

Lymphocyte blastogenesis to Toxoplasma antigens has been used to diagnose congenital toxoplasmosis when the diagnosis is uncertain and other test results are negative. However, a negative result does not exclude the diagnosis because peripheral blood lymphocytes of infected newborns may not respond to T. gondii antigens.

**Acquired Toxoplasmosis**

Recent infection is diagnosed by seroconversion from a negative to a positive IgG antibody titer (in the absence of transfusion); a 2 tube increase in Toxoplasma-specific IgG titer when serial sera are obtained 3 wk apart and tested in parallel; or the detection of Toxoplasma-specific IgM antibody in conjunction with other tests, but never alone.

**Ocular Toxoplasmosis**

IgG antibody titers of 1:4 to 1:64 are usual in older children with active Toxoplasma chorioretinitis. Even the presence of antibodies measurable only when serum is tested undiluted is helpful in establishing the diagnosis. The diagnosis is likely with characteristic retinal lesions and positive serologic tests. PCR of aqueous or vitreous fluid has been used to diagnose ocular toxoplasmosis but is infrequently performed because of the risks associated with obtaining intraocular fluid.

**Immunocompromised Persons**

IgG antibody titers may be low, and Toxoplasma-specific IgM is often absent in immunocompromised stem cell transplant recipients, but not in kidney or heart transplant recipients with toxoplasmosis. Demonstration of Toxoplasma DNA in serum, blood, and CSF may identify disseminated Toxoplasma infection in immunocompromised persons. Resolution of CNS lesions during a therapeutic trial of pyrimethamine and sulfadiazine has been useful to diagnose toxoplasmic encephalitis in patients with AIDS. Brain biopsy has been used to establish the diagnosis if there is no response to a therapeutic trial and to exclude other likely diagnoses such as CNS lymphoma.

**Congenital Toxoplasmosis**

Fetal ultrasound examination, performed every 2 wk during gestation, beginning at the time acute acquired infection is diagnosed in a pregnant woman, and PCR analysis of amniotic fluid are used for prenatal diagnosis. T. gondii may also be isolated from the placenta at birth. PCR of peripheral white blood cells, CSF, and urine has been reported to detect congenital infection.

Lymphocyte blastogenesis to Toxoplasma antigens has been used to diagnose congenital toxoplasmosis when the diagnosis is uncertain and other test results are negative. However, a negative result does not exclude the diagnosis because peripheral blood lymphocytes of infected newborns may not respond to T. gondii antigens.

**Acquired Toxoplasmosis**

Recent infection is diagnosed by seroconversion from a negative to a positive IgG antibody titer (in the absence of transfusion); a 2 tube increase in Toxoplasma-specific IgG titer when serial sera are obtained 3 wk apart and tested in parallel; or the detection of Toxoplasma-specific IgM antibody in conjunction with other tests, but never alone.

**Ocular Toxoplasmosis**

IgG antibody titers of 1:4 to 1:64 are usual in older children with active Toxoplasma chorioretinitis. Even the presence of antibodies measurable only when serum is tested undiluted is helpful in establishing the diagnosis. The diagnosis is likely with characteristic retinal lesions and positive serologic tests. PCR of aqueous or vitreous fluid has been used to diagnose ocular toxoplasmosis but is infrequently performed because of the risks associated with obtaining intraocular fluid.

**Immunocompromised Persons**

IgG antibody titers may be low, and Toxoplasma-specific IgM is often absent in immunocompromised stem cell transplant recipients, but not in kidney or heart transplant recipients with toxoplasmosis. Demonstration of Toxoplasma DNA in serum, blood, and CSF may identify disseminated Toxoplasma infection in immunocompromised persons. Resolution of CNS lesions during a therapeutic trial of pyrimethamine and sulfadiazine has been useful to diagnose toxoplasmic encephalitis in patients with AIDS. Brain biopsy has been used to establish the diagnosis if there is no response to a therapeutic trial and to exclude other likely diagnoses such as CNS lymphoma.

**Congenital Toxoplasmosis**

Fetal ultrasound examination, performed every 2 wk during gestation, beginning at the time acute acquired infection is diagnosed in a pregnant woman, and PCR analysis of amniotic fluid are used for prenatal diagnosis. T. gondii may also be isolated from the placenta at delivery.

Serologic tests are also useful in establishing a diagnosis of congenital toxoplasmosis. Either persistent or rising titers in the dye test or IFA test, or a positive IgM-ELISA or IgM-ISAGA result is diagnostic of congenital toxoplasmosis. The half-life of IgM is approximately 2 days, so if there is a placental leak, the level of IgM antibodies in the infant’s serum decreases significantly, usually within 1 wk. Passively transferred maternal IgG antibodies may require many months to a year to disappear from the infant’s serum, depending on the magnitude of the original titer. The half-life of passively transferred maternal IgG is approximately 30 days, so the titer diminishes by half each 30 days. Synthesis of Toxoplasma antibody is usually demonstrable by the 3rd mo of life if the infant is untreated, although the rate of IgG synthesis varies considerably in infants younger than 1 year of age. If the infant is treated, synthesis may be delayed for as long as the 9th mo of life and, infrequently, may not occur at all. When an infant begins to synthesize IgG antibody, infection may be documented serologically even without demonstration of IgM antibodies by an increase in the ratio of specific serum IgG antibody titer to the total IgG, whereas the ratio will decrease if the specific IgG antibody has been passively transferred from the mother.

Newborns suspected of having congenital toxoplasmosis should be evaluated by general, ophthalmologic, and neurologic examinations; head CT scan; attempt to isolate T. gondii from the placenta and infant’s leukocytes from peripheral blood buffy coat; measurement of serum Toxoplasma-specific IgG, IgM, IgA, and IgE antibodies, and the levels
of total serum IgM and IgG; lumbar puncture including analysis of CSF for cells, glucose, protein, Toxoplasma-specific IgG and IgM antibodies, and level of total IgG; and testing of CSF for T. gondii by PCR and inoculation into mice. Presence of Toxoplasma-specific IgM in CSF that is not contaminated with blood or confirmation of local antibody production of Toxoplasma-specific IgG antibody in CSF establishes the diagnosis of congenital Toxoplasma infection.

Many manifestations of congenital toxoplasmosis are similar to findings that occur in other perinatal infections, especially congenital cytomegalovirus infection. Thus, neither cerebral calcification nor choriorretinitis is pathognomonic. The clinical picture in the newborn infant may also be compatible with sepsis, aseptic meningitis, syphilis, or hemolytic disease. Some children younger than 5 yr of age with choriorretinitis have postnatally acquired T. gondii infection.

**TREATMENT**

Pyrimethamine and sulfadiazine act synergistically against Toxoplasma, and combination therapy is indicated for many of the forms of toxoplasmosis. Use of pyrimethamine is contraindicated during the 1st trimester of pregnancy. Spiramycin should be used to attempt to prevent vertical transmission of infection to the fetus of acutely infected pregnant women. Pyrimethamine inhibits the enzyme dihydrofolate reductase, and thus the synthesis of folic acid, and therefore produces a dose-related, reversible, and usually gradual depression of the bone marrow. Neutropenia is most common but rarely treatment has been reported to result in thrombocytopenia and anemia. Reversible neutropenia is the most common adverse effect in treated infants. All patients treated with pyrimethamine should have platelet and leukocyte counts twice weekly. Seizures may occur with overdosage of pyrimethamine. Folinic acid, as calcium leucovorin, should always be administered concomitantly and for 1 wk after treatment with pyrimethamine is discontinued to prevent bone marrow suppression. Potential toxic effects of sulfonamides (e.g., crystalluria, hematuria, and rash) should be monitored. Hypersensitivity reactions occur, especially in patients with AIDS.

**Acquired Toxoplasmosis**

Patients with acquired toxoplasmosis and lymphadenopathy usually do not need specific treatment unless they have severe and persistent symptoms or evidence of damage to vital organs (see Table 290-2). If such signs and symptoms occur, treatment with pyrimethamine, sulfadiazine, and leucovorin should be initiated. Patients who appear to be immunocompetent but have severe and persistent symptoms or damage to vital organs (e.g., choriorretinitis, myocarditis) need specific therapy until these specific symptoms resolve, followed by therapy for an additional 2 wk. Therapy often is administered for at least 4-6 wk. The optimal duration of therapy is unknown. A loading dose of pyrimethamine for older children is 2 mg/kg/day divided bid (maximum: 50 mg/bid), given for the 1st 2 days of treatment. The maintenance dose begins on the 3rd day and is 1 mg/kg/day (maximum: 50 mg/day). Sulfadiazine is administered at a dosage of 100 mg/kg/day divided bid (maximum: 4 g/day). Leucovorin is administered orally at a dosage of 5-20 mg 3 times a week (or even daily depending on the leukocyte count).

**Ocular Toxoplasmosis**

Patients with active ocular toxoplasmosis are treated with pyrimethamine, sulfadiazine, and leucovorin (see Table 290-2). They are treated while disease is active and then for approximately 1 wk after the lesion has developed a quiescent appearance (i.e., sharp borders, pigmentation at margins of the lesion, and resolution of associated inflammatory cells in the vitreous), which usually occurs in 2-4 wk when treatment is initiated promptly. Within 7-10 days the borders of the retinal lesions sharpen, and visual acuity usually returns to that noted before development of the acute lesion. Systemic corticosteroids have been administered concomitantly with antimicrobial treatment when lesions involve the macula, optic nerve head, or papillomacular bundle. Corticosteroids are never given alone and are begun after loading doses of pyrimethamine and sulfadiazine have been administered (2 days). With recurrences, new lesions often appear contiguous to old ones. Very rarely, vitrectomy and removal of the lens are needed to restore visual acuity. Suppressive treatment has prevented frequent recurrences of vision-threatening lesions.

Active choroidal neovascular membranes as a result of toxoplasmic chorioretinitis have been treated successfully in children with intravitreal injection of antibody to vascular endothelial growth factor in addition to oral anti-Toxoplasma medicines.

**Immunocompromised Persons**

Serologic evidence of acute infection in an immunocompromised patient, regardless of whether signs and symptoms of infection are present or tachyzoites are demonstrated in tissue, are indications for therapy similar to that described for immunocompetent persons with symptoms of organ injury (see Table 290-2). It is important to establish the diagnosis as rapidly as possible and institute treatment early. In immunocompromised patients other than those with AIDS, therapy should be continued for at least 4-6 wk beyond complete resolution of all signs and symptoms of active disease and resolution of cause for immune suppression. Careful follow-up observation of these patients is imperative because relapse may occur, requiring prompt reinstitution of therapy. Relapse used to be frequent in patients with AIDS without antiretroviral treatment, and suppressive therapy with pyrimethamine and sulfonamides, or trimethoprim-sulfamethoxazole, was continued for life. Now it is possible to discontinue maintenance therapy when the CD4 count remains >200 cells/µL for 4 mo and all lesions have resolved. Therapy usually induces a beneficial response clinically, but it does not eradicate cysts. Treatment of T. gondii–seropositive patients with AIDS should be continued as long as CD4 counts remain <200 cells/µL. Prophylactic treatment with trimethoprim-sulfamethoxazole for Pneumocystis carinii pneumonia significantly reduces the incidence of toxoplasmosis in patients with AIDS.

**Congenital Toxoplasmosis**

All fetuses and newborns infected with T. gondii should be treated whether or not they have clinical manifestations of the infection because treatment may be effective in interrupting acute disease that damages vital organs (see Table 290-2 and Fig. 290-5). The fetus is treated by treating the pregnant woman with pyrimethamine and sulfadiazine (with leucovorin). Infants should be treated for 1 yr with pyrimethamine (2 mg/kg/day divided bid for 2 days, then beginning on the 3rd day, 1 mg/kg/day for 2 or 6 mo, and then 1 mg/kg given on Monday, Wednesday, and Friday, PO), sulfadiazine (100 mg/kg/day divided bid PO), and leucovorin (5-10 mg given on Monday, Wednesday, and Friday, or more often depending on neutrophil count, PO). The relative efficacy in reducing sequelae of infection and the safety of treatment with 2 vs 6 mo of the higher dosage of pyrimethamine are being compared in the U.S. National Collaborative Study. Updated information about this study and these regimens is available from Dr. Rima McLeod (773-834-4131). Pyrimethamine and sulfadiazine are available only in tablet form and can be prepared as suspensions. Prednisone (1 mg/kg/day divided bid PO) has been used in addition when active chorioretinitis involves the macula or otherwise threatens vision or the CSF protein is >1,000 mg/dL at birth, but the efficacy is not established. Prednisone is continued only for as long as the active inflammatory process in the posterior pole of the eye is vision-threatening or CSF protein is >1,000 mg/dL and then tapered rapidly if the duration of treatment has been brief.

**Pregnant Women with Toxoplasma gondii Infection**

The immunologically normal pregnant woman who acquired T. gondii more than 6 mo before conception does not need treatment to prevent congenital infection of her fetus. Although data are not available to allow for a definitive time interval, if infection occurs during or shortly before the pregnancy, it is reasonable to evaluate the fetus by use of PCR with amniotic fluid and ultrasonography and treat to prevent congenital infection in the fetus (see Table 290-2).

Treatment of a pregnant woman who acquires infection at any time during pregnancy reduces the chance of congenital infection in her

- **Medication:** Sulfadiazine, Pyrimethamine, Folinic acid (calcium leucovorin)
- **Concentration:** 100mg/mL, 2mg/mL, 5mg/tablet
- **Dispense:** 50ml *, 25mL *
- **Dosage:** Half of infant's current weight in kg equals number of ml given in AM and PM
  - Half of infant's current weight in kg equals number of ml given once daily
    - 10mg (two 5mg tablets) on Monday, Wednesday, and Friday
    - Crush and give with formula, water, milk, or juice in one dosage. May adjust based on neutrophil count.

* Suspended in 2% sugar solution. Suspension at usual concentration must be made each week. Store refrigerated.
* e.g. If infant weighs 5kg, give 2.5ml at 3AM and 7PM.
# e.g. If infant weighs 8kg, give 2.5ml daily.
$ for pyrimethamine, first loading dose is 1mg/kg given 8ID for 2 days. Beginning third day, dose is 1mg/kg per day.

Infant. Spiramycin (1 g every 8 hr PO without food) is recommended for prevention of fetal infection if the mother develops acute toxoplasmosis during pregnancy. Spiramycin is available in the United States upon an “emergency use” request by a physician through the FDA Division of Anti-Infective Drugs (301-796-1400) after the diagnosis of acute infection is confirmed in a reference laboratory (Palo Alto Medical Facility Toxoplasma Serology Lab 650-853-4828). With this approval, the physician can then contact the spiramycin manufacturer, Sanofi Pasteur (1-800-822-2463), to obtain spiramycin for the patient. Adverse reactions are infrequent and include paresthesia, rash, nausea, vomiting, and diarrhea. Following a loading dose of pyrimethamine (50 mg divided bid) for 2 days, beginning on the 3rd day, pyrimethamine is administered at a dose of 50 mg once daily. Beginning on the 1st day of treatment with pyrimethamine, sulfadiazine (1.5-2.0 g bid PO), and leucovorin (10 mg once daily PO) are recommended for treatment of the pregnant woman whose fetus has confirmed or probable fetal infection except in the 1st trimester. In the 1st trimester, when there is definite infection, sulfadiazine alone is recommended because pyrimethamine is potentially teratogenic at that time. Spiramycin treatment is used for infection acquired early in gestation when it is uncertain whether there is fetal infection. Treatment of the mother of an infected fetus with pyrimethamine and sulfadiazine reduces infection in the placenta and the severity of disease in the newborn. Delay in maternal treatment during gestation results in greater brain and eye disease in the infant. Diagnostic amniocentesis should be performed at ≥17-18 wk of gestation in pregnancies when there is high suspicion of fetal infection. Overall sensitivity of PCR for amniotic fluid is at 85% between 17 and 21 wk of gestation. The sensitivity of PCR using amniotic fluid for diagnosis of fetal infection is 92% in early and late gestation. Ultrasoundography and amniocentesis for PCR at approximately 18 wk of gestation are used for fetal diagnosis and have 97% sensitivity and 100% specificity. Confidence intervals for sensitivity are largest early and late in gestation. Fetal infection is treated with pyrimethamine and sulfadiazine. Termination of pregnancy is very rare at present. Prompt initiation of treatment with pyrimethamine and sulfadiazine during pregnancy usually has an excellent outcome, with normal development of children. Only 19% have subtle findings of congenital infection, including intracranial calcifications (13%) and chorioretinal scars (6%), although 39% have chorioretinal scars detected at follow-up observation during later childhood. Several studies have demonstrated improved outcomes with shorter times between diagnosis and initiation of treatment.

Chronically infected pregnant women who are immunocompromised have transmitted *T. gondii* to their fetuses. Such women should be treated with spiramycin throughout gestation. The optimal management for prevention of congenital toxoplasmosis in the fetus of a pregnant woman with HIV infection with a CD4 count ≤200 cells/µL and inactive *T. gondii* infection is unknown. If the pregnancy is not terminated, some investigators suggest that the mother should be treated with spiramycin during the 1st 14 wk of gestation and thereafter with pyrimethamine and sulfadiazine until term. There are no universally accepted guidelines at present. In a study of adult patients with AIDS and toxoplasmic encephalitis, pyrimethamine (75 mg once daily PO) combined with high dosages of intravenously administered clindamycin (1,200 mg every 6 hr IV) appeared equal in efficacy to sulfadiazine and pyrimethamine in the treatment of the toxoplasmic encephalitis. Other experimental agents include the macrolides clarithromycin and azithromycin.

**PROGNOSIS**

Early institution of specific treatment for congenitally infected infants usually cures the active manifestations of toxoplasmosis, including active chorioretinitis, meningitis, encephalitis, hepatitis, splenomegaly, and thrombocytopenia. Rarely, hydrocephalus resulting from atheroocclusive obstruction may develop or become worse during therapy. Treatment appears to reduce the incidence of some sequelae such as diminished cognitive and abnormal motor function. Without therapy and in some treated patients as well, chorioretinitis often recurs. Children with extensive involvement at birth may function normally later in life or have mild to severe impairment of vision, hearing, cognitive...
function, and other neurologic functions. Delays in diagnosis and therapy, perinatal hypoglycemia, hypoxia, hypotension, repeated shunt infections, and severe visual impairment are associated with a poorer prognosis. The prognosis is not necessarily poor for infected babies. It should be understood, however, that treatment with pyrimethamine and sulfadiazine does not eradicate encysted parasites.

Studies in Lyon and Paris, France, demonstrated that outcome of treated fetal toxoplasmosis, even when infection is acquired early in gestation, is usually favorable if no hydrocephalus is detected on ultrasound, and treatment with pyrimethamine and sulfadiazine is initiated promptly. The SYROCOT (Systematic Review on Congenital Toxoplasmosis) study in Europe indicated that neurologic outcome is improved with shorter times between diagnosis and initiation of treatment of fetal toxoplasmosis. Work in Lyon, France, has indicated a low incidence of recurrent eye disease in children with congenital toxoplasmosis who had been treated in utero and in their 1st yr of life. The National Collaborative Chicago-Based Congenital Toxoplasmosis Study (NCCCTS) (1981-2004) in the United States found that neurologic, developmental, audiologic, and ophthalmologic outcomes are considerably better for most, but not all, children who were treated in their 1st yr of life with pyrimethamine and sulfadiazine (with leucovorin) when compared to children who had not been treated or were treated for only 1 mo in earlier decades described in the literature. The mean age of the children in this study was 10.8 yr at the time of this analysis, when most of the children had not yet entered their teenage years. Recurrent disease, if it occurs, appears most commonly during adolescence.

PREVENTION
Counseling pregnant women about the methods of preventing transmission of *T. gondii* (see Fig. 290-1) during pregnancy can reduce acquisition of infection during gestation. Women who do not have specific antibody to *T. gondii* before pregnancy should only eat well-cooked meat during pregnancy and avoid contact with oocysts excreted by cats. Cats that are kept indoors, maintained on prepared food, and not fed fresh, uncooked meat should not contact encysted *T. gondii* or shed oocysts. Serologic screening, ultrasound monitoring, and treatment of pregnant women during gestation can also reduce the incidence and manifestations of congenital toxoplasmosis. No protective vaccine is available.

Ascariasis (Ascaris lumbricoides)

ETIOLOGY
Ascariasis is caused by the nematode, or roundworm, *Ascaris lumbricoides*. Adult worms of *A. lumbricoides* inhabit the lumen of the small intestine and have a life span of 10-24 mo. The reproductive potential of *Ascaris* is prodigious; a gravid female worm produces 200,000 eggs per day. The fertile ova are oval in shape with a thick mammillated covering measuring 45-70 µm in length and 35-50 µm in breadth (Fig. 291-1). After passage in the feces, the eggs embryonate and become infective in 5-10 days under favorable environmental conditions. Adult worms can live for 12-18 mo (Fig. 291-2).

EPIEMIOLOGY
Ascariasis occurs globally and is the most prevalent human helminthiasis in the world. It is most common in tropical areas of the world where environmental conditions are optimal for maturation of ova in the soil. Approximately 1 billion persons are estimated to be infected. Although the number of cases in the United States is not known precisely, the highest prevalence is thought to be in high poverty areas of the South and Appalachia. Pig farming in Maine is also associated with *Ascaris* species. Key factors linked with a higher prevalence of infection include poor socioeconomic conditions, use of human feces as fertilizer, and geophagia. Even though infection can occur at any age, the highest rate is in preschool or early school-age children. Transmission is primarily hand to mouth, but may also involve ingestion of contaminated raw fruits and vegetables. Transmission is enhanced by the high output of eggs by fecund female worms and resistance of ova to the outside environment. *Ascaris* eggs can remain viable at 5-10°C (41-50°F) for as long as 2 yr.

PATHOGENESIS
*Ascaris* ova hatch in the small intestine after ingestion by the human host. Larvae are released, penetrate the intestinal wall, and migrate to
the lungs by way of the venous circulation. The parasites then cause **pulmonary ascariasis** as they enter into the alveoli and migrate through the bronchi and trachea. They are subsequently swallowed and return to the intestines, where they mature into adult worms. Female *Ascaris* begin depositing eggs in 8-10 wk.

**CLINICAL MANIFESTATIONS**

The clinical presentation depends on the intensity of infection and the organs involved. Most individuals have low to moderate worm burdens and have no symptoms or signs. The most common clinical problems are from **pulmonary disease** and **obstruction of the intestinal or biliary tract**. Larvae migrating through these tissues may cause allergic symptoms, fever, urticaria, and granulomatous disease. The pulmonary manifestations resemble Loeffler syndrome and include transient respiratory symptoms such as cough and dyspnea, pulmonary infiltrates, and blood eosinophilia. Larvae may be observed in the sputum. Vague abdominal complaints have been attributed to the presence of adult worms in the small intestine, although the precise contribution of the parasite to these symptoms is difficult to ascertain. A more serious complication occurs when a large mass of worms leads to acute bowel obstruction. Children with heavy infections may present with vomiting, abdominal distention, and cramps. In some cases, worms may be passed in the vomitus or stools. *Ascaris* worms occasionally migrate into the biliary and pancreatic ducts, where they cause cholecystitis or pancreatitis. Worm migration through the intestinal wall can lead to peritonitis. Dead worms can serve as a nidus for stone formation. Studies show that chronic infection with *A. lumbricoides* (often coincident with other helminth infections) impairs growth, physical fitness, and cognitive development.

**DIAGNOSIS**

Microscopic examination of fecal smears can be used for diagnosis because of the high number of eggs excreted by adult female worms (see **Fig. 291-1**). A high index of suspicion in the appropriate clinical context is needed to diagnose pulmonary ascariasis or obstruction of the gastrointestinal tract. Ultrasound examination of the abdomen is capable of visualizing intraluminal adult worms.

**TREATMENT**

Although several chemotherapeutic agents are effective against ascariasis, none has documented utility during the pulmonary phase of infection. Treatment options for gastrointestinal ascariasis include albendazole (400 mg PO once, for all ages), mebendazole (100 mg PO bid for 3 days or 500 mg once for all ages), or ivermectin (150-200 µg/kg PO once). Piperazine citrate (75 mg/kg/day for 2 days; maximum: 3.5 g/day), which causes neuromuscular paralysis of the parasite and rapid expulsion of the worms, is the treatment of choice for intestinal or biliary obstruction and is administered as syrup through a nasogastric tube. Surgery may be required for cases with severe obstruction. Nitazoxanide (100 mg PO bid for 3 days for children 1-3 yr of age, 200 mg bid for 3 days for children 4-11 yr, and 500 mg bid for 3 days for adolescents and adults) produces cure rates comparable to single-dose albendazole. Drug resistance has not been reported, but repeated treatment for ascariasis may be necessary because reinfection is common.

**PREVENTION**

Although ascariasis is the most prevalent worm infection in the world, little attention has been given to its control. Anthelmintic chemotherapy programs can be implemented in 1 of 3 ways: (1) offering universal treatment to all individuals in an area of high endemicity; (2) offering treatment targeted to groups with high frequency of infection, such as children attending primary school; or (3) offering individual treatment based on intensity of current or past infection. Improving education about and practices of sanitary conditions and sewage facilities, discontinuing the practice of using human feces as fertilizer, and education are the most effective long-term preventive measures.

Bibliography

ETIOLOGY
Two major genera of hookworms, which are nematodes or roundworms, infect humans. *Necator americanus*, the only representative of its genus, is a major anthropophilic hookworm and is the most common cause of human hookworm infection. Hookworms of the genus *Ancylostoma* include the anthropophilic hookworm *Ancylostoma duodenale* that also causes classic hookworm infection and the less common zoonotic species *Ancylostoma ceylanicum*, *Ancylostoma caninum*, and *Ancylostoma braziliense*. Human zoonotic infection with the dog hookworm *A. caninum* is associated with an eosinophilic enteritis syndrome. The larval stage of *A. braziliense*, whose definitive hosts include dogs and cats, is the principal cause of cutaneous larva migrans.

The infective larval stages of the anthropophilic hookworms live in a developmentally arrested state in warm, moist soil. Larvae infect humans either by penetrating through the skin (*N. americanus* and *A. duodenale*) or when they are ingested (*A. duodenale*). Larvae entering the human host by skin penetration undergo extraintestinal migration through the venous circulation and lungs before they are swallowed, whereas orally ingested larvae may undergo extraintestinal migration or remain in the gastrointestinal tract. Larvae returning to the small intestine undergo 2 molts to become adult, sexually mature, male and female worms ranging in length from 5-13 mm. The buccal capsule of the adult hookworm is armed with cutting plates (*N. americanus*) or teeth (*A. duodenale*) to facilitate attachment to the mucosa and submucosa of the small intestine. Hookworms can remain in the intestine for 1-5 yr, where they mate and produce eggs. Although up to 2 mo is required for the larval stages of hookworms to undergo extraintestinal migration and develop into mature adults, *A. duodenale* larvae may remain developmentally arrested for many months before resuming development in the intestine. Mature *A. duodenale* female worms produce about 30,000 eggs per day; daily egg production by *N. americanus* is <10,000/day (Fig. 292-1). The eggs are thin shelled and ovoid, measuring approximately 40-60 µm. Eggs that are deposited on soil with adequate moisture and shade develop into first-stage larvae and hatch. Over the ensuing several days and under appropriate conditions, the larvae molt twice to the infective stage. Infective larvae are developmentally arrested and nonfeeding. They migrate vertically in the soil until they either infect a new host or exhaust their lipid metabolic reserves and die.

EPIDEMIOLOGY
Hookworm infection is one of the most prevalent infectious diseases of humans, affecting an estimated 600-700 million individuals worldwide. New information from the Global Burden of Disease 2010 Study indicates that hookworm infection leads all neglected tropical diseases in years lost through disability. In the case of hookworm infection, all of the years lost through disability are attributed to anemia from intestinal blood loss.

Because of the requirement for adequate soil moisture, shade, and warmth, hookworm infection is usually confined to rural areas, especially where human feces are used for fertilizer or where sanitation is inadequate. Hookworm is an infection associated with economic underdevelopment and poverty throughout the tropics and subtropics. Sub-Saharan Africa, East Asia, and tropical regions of the Americas...
have the highest prevalence of hookworm infection. High rates of infection are often associated with cultivation of certain agricultural products such as tea in India; sweet potato, corn, cotton, and mulberry trees in China; coffee in Central and South America; and rubber in Africa. It is not uncommon to find dual *N. americanus* and *A. duodenale* infections. *N. americanus* predominates in Central and South America as well as in southern China and southeast Asia, whereas *A. duodenale* predominates in North Africa, in northern India, in China north of the Yangtze River, and among aboriginal people in Australia. The ability of *A. duodenale* to withstand somewhat harsher environmental and climatic conditions may reflect its ability to undergo arrested development in human tissues. *A. ceylanicum* infection occurs in India and Southeast Asia.

**Eosinophilic enteritis** caused by *A. caninum* was first described in Queensland, Australia, with 2 reported cases in the United States. Because of its global distribution in dogs, it was initially anticipated that human *A. caninum* infections would be identified in many locales, but this has not been found.

**PATHOGENESIS**

The major morbidity of human hookworm infection is a direct result of intestinal blood loss. Adult hookworms adhere tenaciously to the mucosa and submucosa of the proximal small intestine by using their cutting plates or teeth and a muscular esophagus that creates negative pressure in their buccal capsules. At the attachment site, host inflammation is downregulated by the release of antiinflammatory polypeptides by the hookworm. Rupture of capillaries in the lamina propria is followed by blood extravasation, with some of the blood ingested directly by the hookworm. After ingestion, the blood is anticoagulated, the red blood cells are lysed, and the hemoglobin released and digested. Each adult *A. duodenale* hookworm causes loss of an estimated 0.2 mL of blood/day; blood loss is less for *N. americanus*. Individuals with light infections suffer from very little blood loss and, consequently, may have hookworm infection but not hookworm disease. There is a direct correlation between the number of adult hookworms in the gut and the volume of fecal blood loss. Hookworm disease results only when individuals with moderate and heavy infections experience sufficient blood loss to develop iron deficiency and anemia. Hypoalbuminemia and consequent edema and anasarca from the loss of intravascular oncotic pressure can also occur. These features depend heavily on the dietary reserves of the host.

**CLINICAL MANIFESTATIONS**

Chromically infected children with moderate and heavy hookworm infections suffer from intestinal blood loss that results in iron deficiency and can lead to anemia as well as protein malnutrition. Prolonged iron deficiency associated with hookworms in childhood can lead to physical growth retardation and cognitive and intellectual deficits.

Anthropophilic hookworm larvae elicit dermatitis sometimes referred to as ground itch when they penetrate human skin. The vesiculation and edema of ground itch are exacerbated by repeated infection. Infection with a zoonotic hookworm, especially *A. braziliense*, can result in lateral migration of the larvae to cause the characteristic cutaneous tracts of cutaneous larva migrans (see Chapter 292.1). Cough subsequently occurs in *A. duodenale* and *N. americanus* hookworm infection when larvae migrate through the lungs to cause laryngotracheobronchitis, usually about 1 wk after exposure. Pharyngitis also can occur. The onset of eosinophilia coincides with the entry of hookworm larvae into the gastrointestinal tract. Upper abdominal pain can occur during this period, but it eventually subsides.

Chronic intestinal hookworm infection is not typically associated with specific gastrointestinal complaints, although pain, anorexia, and diarrhea have been attributed to the presence of hookworms. The major clinical manifestations are related to intestinal blood loss. Heavily infected children exhibit all of the signs and symptoms of iron deficiency anemia and protein malnutrition. In some cases, children with chronic hookworm disease acquire a yellow-green pallor known as chlorosis.

An infantile form of ancylostomiasis resulting from heavy *A. duodenale* infection has been described. Affected infants experience diarrhea, melena, failure to thrive, and profound anemia. Infantile ancylostomiasis has significant mortality.

**Eosinophilic enteritis** caused by *A. caninum* is associated with colicky abdominal pain that begins in the epigastrium and radiates outward and is usually exacerbated by food. Extreme cases may mimic acute appendicitis.

**DIAGNOSIS**

Children with hookworm release eggs that can be detected by direct fecal examination (Fig. 292-2). Quantitative methods are available to determine whether a child has a heavy worm burden that can cause hookworm disease. The eggs of *N. americanus* and *A. duodenale* are morphologically indistinguishable. Species identification typically requires egg hatching and differentiation of third-stage infective larvae; newer methods using polymerase chain reaction methods have been developed but are not generally used in clinical practice.

In contrast, eggs are generally not present in the feces of patients with eosinophilic enteritis caused by *A. caninum*. Eosinophilic enteritis is often diagnosed by demonstrating ileal and colonic ulcerations by colonoscopy in the presence of significant blood eosinophilia. An adult canine hookworm may occasionally be recovered during colonoscopic biopsy. Patients with this syndrome develop immunoglobulin G and immunoglobulin E serologic responses.

**TREATMENT**

The goal of deworming is removal of the adult hookworms with an anthelmintic drug. The benzimidazoles anthelmintics, mebendazole and albendazole, are effective at eliminating hookworms from the...
Cutaneous larva migrans (creeping eruption) is caused by the larvae of several nematodes, primarily hookworms, which are not usually parasitic for humans. *A. braziliense*, a hookworm of dogs and cats, is the most common cause, but other animal hookworms may also produce the disease.

**DIAGNOSIS**

Cutaneous larva migrans is diagnosed by clinical examination of the skin. Patients are often able to recall the exact time and location of exposure, because the larvae produce intense itching at the site of penetration. Eosinophilia may occur but is uncommon.

**TREATMENT**

If left untreated, the larvae die, and the syndrome resolves within a few weeks to several months. Treatment with ivermectin (200 µg/kg daily PO for 1-2 days; considered the drug of choice by some investigators), albendazole (400 mg daily PO for 3 days, for all ages), or topical thiabendazole hastens resolution, if symptoms warrant treatment. Nausea and vomiting frequently preclude repeated administration of oral thiabendazole. The safety of ivermectin in young children (weighing <15 kg) and pregnant women remains to be established. Ivermectin should be taken on an empty stomach with water, whereas albendazole should be taken with a fatty meal.

Bibliography is available at Expert Consult.

---

**PREVENTION**

In 2001, the World Health Assembly urged its member states to implement programs of periodic deworming so as to control the morbidity of hookworm and other soil-transmitted helminth infections. Although anthelmintic drugs are effective at eliminating hookworms from the intestine, the high rates of drug failure from single-dose mebendazole and posttreatment reinfection among children suggest that mass drug administration alone is not effective for controlling hookworm in highly endemic areas. Moreover, data suggest that the efficacy of mebendazole decreases with frequent, periodic use, leading to concerns about the possible emergence of anthelmintic drug resistance. To reduce the reliance exclusively on anthelmintic drugs, a recombinant human hookworm vaccine has been developed and is undergoing clinical testing. Economic development and associated improvements in sanitation, health education, and avoidance of human feces as fertilizer remain critical for reducing hookworm transmission and endemicity.

Bibliography is available at Expert Consult.

---

**CLINICAL MANIFESTATIONS**

After penetrating the skin, larvae localize at the epidermal-dermal junction and migrate in this plane, moving at a rate of 1-2 cm/day. The response to the parasite is characterized by raised, erythematous, serpiginous tracks, which occasionally form bullae (Fig. 292-3). These lesions may be single or numerous and are usually localized to an extremity, although any area of the body may be affected. As the organism migrates, new areas of involvement may appear every few days. Intense localized pruritus, without any systemic symptoms, may be associated with the lesions. Bacterial superinfection can occur.

---

**ETIOLOGY**

Cutaneous larva migrans is usually caused by *A. braziliense*, which is endemic to the southeastern United States and Puerto Rico. Travelers account for a significant percentage of the cases.
Bibliography

Bibliography

ETIOLOGY
Trichuriasis is caused by the whipworm, Trichuris trichiura, a nematode, or roundworm, that inhabits the cecum and ascending colon. The principal hosts of T. trichiura are humans who acquire infection by ingesting embryonated, barrel-shaped eggs (Fig. 293-1). The larvae escape from the shell in the upper small intestine and penetrate the intestinal villi. The worms slowly move toward the cecum, where the...
developmental and cognitive deficits. There is no significant eosinophilia, even though a portion of the worm is embedded in the mucosa of the large bowel.

**DIAGNOSIS**

Because egg output is so high, fecal smears frequently reveal the characteristic barrel-shaped ova of *T. trichiura*.

**TREATMENT**

Albendazole (400 mg PO for 3 days for all ages) is the drug of choice and is safe and effective, in part because it is poorly absorbed from the gastrointestinal tract. It reduces egg output by 90-99% and has cure rates of 70-90%, although reinfection and resumption of egg production by live worms that presumably survive after treatment may occur. Alternatives include mebendazole (100 mg PO bid for 3 days) and ivermectin (200 µg/kg PO for 3 days). Single-day treatment with albendazole, nitazoxanide, or albendazole plus nitazoxanide lead to cure rates that are low and short-lived. Combination treatment with oxantel pamoate (20 mg/kg) plus 400 mg albendazole on consecutive days may have the highest cure rate.

**PREVENTION**

Disease can be prevented by personal hygiene, improved sanitary conditions, and eliminating the use of human feces as fertilizer.

**CLINICAL MANIFESTATIONS**

Most persons harbor low worm burdens and do not have symptoms. Some individuals may have a history of right-lower-quadrant or vague periumbilical pain. Adult *Trichuris* suck approximately 0.005 mL of blood per worm per day. Children, who are most likely to be heavily infected, frequently suffer from disease. Clinical manifestations include chronic dysentery, rectal prolapse, anemia, poor growth, as well as
Bibliography

ETIOLOGY
The cause of enterobiasis, or pinworm infection, is *Enterobius vermicularis*, which is a small (1 cm in length), white, threadlike nematode, or roundworm, that typically inhabits the cecum, appendix, and adjacent areas of the ileum and ascending colon. Gravid females migrate at night to the perianal and perineal regions, where they deposit up to 15,000 eggs. Ova are convex on 1 side and flattened on the other and have diameters of approximately $30 \times 60 \, \mu m$. Eggs embryonate within 6 hr and remain viable for 20 days. Human infection occurs by the fecal-oral route typically by ingestion of embryonated eggs that are carried on fingernails, clothing, bedding, or house dust. After ingestion, the larvae mature to form adult worms in 36-53 days.

EPIDEMIOLOGY
Enterobiasis infection occurs in individuals of all ages and socioeconomic levels. It is prevalent in regions with temperate climates and is the most common helminth infection in the United States. It infects 30% of children worldwide, and humans are the only known host. Infection occurs primarily in institutional or family settings that include children. The prevalence of pinworm infection is highest in children 5-14 yr of age. It is common in areas where children live, play, and sleep close together, thus facilitating egg transmission. Because the life span of the adult worm is short, chronic parasitism is likely due to repeated cycles of reinfection. Autoinoculation can occur in individuals who habitually put their fingers in their mouth.
PATHOGENESIS

Enterobius infection may cause symptoms by mechanical stimulation and irritation, allergic reactions, and migration of the worms to anatomic sites where they become pathogenic. Enterobius infection has been associated with concomitant Dientamoeba fragilis infection, which causes diarrhea.

CLINICAL MANIFESTATIONS

Pinworm infection is innocuous and rarely causes serious medical problems. The most common complaints include itching and restless sleep secondary to nocturnal perianal or perineal pruritus. The precise cause and incidence of pruritus are unknown but may be related to the intensity of infection, psychologic profile of the infected individual and his or her family, or allergic reactions to the parasite. Eosinophilia is not observed in most cases, because tissue invasion does not occur. Aberrant migration to ectopic sites occasionally may lead to appendicitis, chronic salpingitis, pelvic inflammatory disease, peritonitis, hepatitis, and ulcerative lesions in the large or small bowel.

DIAGNOSIS

A history of nocturnal perianal pruritus in children strongly suggests enterobiosis. Definitive diagnosis is established by identification of parasite eggs or worms. Microscopic examination of adhesive cellophane tape pressed against the perianal region early in the morning frequently demonstrates eggs (Fig. 294-1). Repeated examinations increase the chance of detecting ova; a single examination detects 50% of infections, 3 examinations 90%, and 5 examinations 99%. Worms seen in the perianal region should be removed and preserved in 75% ethyl alcohol until microscopic examination can be performed. Digital rectal examination may also be used to obtain samples for a wet mount. Routine stool samples rarely demonstrate Enterobius ova.

TREATMENT

Anthelmintic drugs should be administered to infected individuals and their family members. Albendazole (400 mg PO with a repeat dose 2 wk later for all age groups) is the treatment of choice and results in cure rates exceeding 90%. Alternatives include mebendazole (100 mg PO with a repeat dose 2 wk later) and pyrantel pamoate (11 mg/kg base PO 3 times for 1 day up to a maximum of 1 g; repeat at 2 wk). Morning bathing removes a large portion of eggs. Frequent changing of underclothes, bed clothes, and bed sheets decreases environmental egg contamination and may decrease the risk for autoinfection.

PREVENTION

Household contacts can be treated at the same time as the infected individual. Repeated treatments every 3–4 mo may be required in circumstances with repeated exposure, such as with institutionalized children. Good hand hygiene is the most effective method of prevention.

Chapter 295
Strongyloidiasis
(Strongyloides stercoralis)
Arlene E. Dent and James W. Kazura

ETIOLOGY
Strongyloidiasis is caused by the nematode, or roundworm, Strongyloides stercoralis. Only adult female worms inhabit the small intestine. The nematode reproduces in the human host by parthenogenesis and releases eggs containing mature larvae into the intestinal lumen. Rhabditiform larvae immediately emerge from the ova and are passed in feces, where they can be visualized by stool examination. Rhabditiform larvae either differentiate into free-living adult male and female worms or metamorphose into the infectious filariform larvae. Sexual reproduction occurs only in the free-living stage. Humans are usually infected through skin contact with soil contaminated with infectious larvae. Larvae penetrate the skin, enter the venous circulation and then pass to the lungs, break into alveolar spaces, and migrate up the bronchial tree. They are then swallowed and pass through the stomach, and adult female worms develop in the small intestine. Egg deposition begins approximately 28 days after initial infection.

The hyperinfection syndrome occurs when large numbers of larvae transform into infective organisms during their passage in feces and then reinfect (autoinfect) the host by way of the lower gastrointestinal tract or perianal region. This cycle may be accelerated in immunocompromised persons, particularly those with depressed T-cell function.

EPIDEMIOLOGY
S. stercoralis infection is prevalent in tropical and subtropical regions of the world and is endemic in several areas of Europe, the southern United States, and Puerto Rico. Transmission requires appropriate environmental conditions, particularly warm, moist soil. Poor sanitation and crowded living conditions are conducive to high levels of transmission. Dogs and cats can act as reservoirs. The highest prevalence of infection in the United States (4% of the general population) is in impoverished rural areas of Kentucky and Tennessee. Infection may be especially common among residents of mental institutions, veterans who were prisoners of war in areas of high endemicity, and refugees and immigrants. Because of internal autoinfection, individuals may remain infected for decades. Infection may be transmitted by organ transplantation. Individuals with hematologic malignancies, autoimmune diseases, malnutrition, and drug-induced immunosuppression (especially corticosteroids) are at high risk for the hyperinfection syndrome. Patients with AIDS may experience a rapid course of disseminated strongyloidiasis with a fatal outcome.

PATHOGENESIS
The initial host immune response to infection is production of immunoglobulin E and eosinophilia in blood and tissues, which presumably prevents dissemination and hyperinfection in the immunocompetent host. Adult female worms in otherwise healthy and asymptomatic individuals may persist in the gastrointestinal tract for years. If infected persons become immunocompromised, the reduction in cellular and humoral immunity may lead to an abrupt and dramatic increase in parasite load with systemic dissemination.

CLINICAL MANIFESTATIONS
Approximately 30% of infected individuals are asymptomatic. The remaining patients have symptoms that correlate with the 3 stages of infection: invasion of the skin, migration of larvae through the lungs, and parasitism of the small intestine by adult worms. Larva currens is
the manifestation of an allergic reaction to filariform larvae that migrate through the skin, where they leave pruritic, tortuous, urticarial tracks. The lesions may recur and are typically found over the lower abdominal wall, buttocks, or thighs, resulting from larval migration from defecated stool. Pulmonary disease secondary to larval migration through the lung rarely occurs and may resemble Loeffler syndrome (cough, wheezing, shortness of breath, transient pulmonary infiltrates accompanied by eosinophilia). Gastrointestinal strongyloidiasis is characterized by indigestion, crampy abdominal pain, vomiting, diarrhea, steatorrhea, protein-losing enteropathy, protein-caloric malnutrition, and weight loss. Edema of the duodenum with irregular mucosal folds, ulcerations, and strictures can be seen radiographically. Infection may be chronic in nature and is associated with eosinophilia.

Strongyloidiasis is potentially lethal because of the ability of the parasite to replicate within the host and cause overwhelming hyperinfection in immunocompromised persons. The hyperinfection syndrome is characterized by an exaggeration of the clinical features that develop in symptomatic immunocompetent individuals. The onset is usually sudden, with generalized abdominal pain, distention, and fever. Multiple organs can be affected as massive numbers of larvae disseminate throughout the body and introduce bowel flora. The latter may result in bacteremia and septicemia. Cutaneous manifestations may include petechiae and purpura. Cough, wheezing, and hemoptysis are indicative of pulmonary involvement. Whereas eosinophilia is a prominent feature of strongyloidiasis in immunocompetent persons, this sign may be absent in immunocompromised persons. Because of the low incidence of strongyloidiasis in industrialized countries, it is often misdiagnosed, resulting in a significant delay in treatment.

**DIAGNOSIS**

Intestinal strongyloidiasis is diagnosed by examining feces or duodenal fluid for the characteristic larvae (Fig. 295-1). Several stool samples should be examined either by direct smear, the Koga agar plate method, or the Baermann test. Alternatively, duodenal fluid can be sampled by the enteric string test (Entero-Test) or aspiration via endoscopy. In children with the hyperinfection syndrome, larvae may be found in sputum, gastric aspirates, and, rarely, in small intestinal biopsy specimens. An enzyme-linked immunosorbent assay for immunoglobulin G antibody to Strongyloides may be more sensitive than parasitologic methods for diagnosing intestinal infection in the immunocompetent host. The utility of the assay in diagnosing infection in immunocompromised subjects with the hyperinfection syndrome has not been determined. Eosinophilia is common.

**TREATMENT**

Treatment is directed at eradication of infection. Ivermectin (200 µg/kg/day once daily PO for 2 days) is the drug of choice for uncomplicated strongyloidiasis. Alternatively, albendazole (400 mg PO twice daily for 7 days) may be used. Patients with the hyperinfection syndrome should be treated with ivermectin for 7-10 days and may require repeated courses. Reducing the dose of immunosuppressive therapy and treatment of concomitant bacterial infections are essential in the management of the hyperinfection syndrome. Close follow-up with repeated stool examination is necessary to ensure complete elimination of the parasite. Strongyloides antibodies decrease within 6 mo after successful treatment.

**PREVENTION**

Sanitary practices designed to prevent soil and person-to-person transmission are the most effective control measures. Wearing shoes is a main preventive strategy. Reduction in transmission in institutional settings can be achieved by decreasing fecal contamination of the environment such as by the use of clean bedding. Because infection is uncommon in most settings, case detection and treatment are advisable. Individuals who will be given prolonged high-dose corticosteroids, immunosuppressive drugs before organ transplantation, or cancer chemotherapy should have a screening examination for S. stercoralis. If infected, they should be treated before immunosuppression is initiated.

ETIOLOGY
The filarial worms *Brugia malayi* (Malayan filariasis), *Brugia timori*, and *Wuchereria bancrofti* (bancroftian filariasis) are threadlike nematodes that cause similar infections. Infective larvae are introduced into humans during blood feeding by the mosquito vector. Over a period of 4-6 mo, the larval forms develop into sexually mature adult worms. Once an adequate number of male and female worms accumulate in the afferent lymphatic vessels, adult female worms release large numbers of microfilariae that circulate in the bloodstream. The life cycle of the parasite is completed when mosquitoes ingest microfilariae
in a blood meal, which molt to form infective larvae over a period of 10-14 days. Adult worms have a 5-7 yr life span.

EPIDEMIOLOGY
More than 120 million people living in tropical Africa, Asia, and Latin America are infected; approximately 10-20% of these individuals have clinically significant morbidity attributable to filariasis. W. bancrofti is transmitted in Africa, Asia, and Latin America and accounts for 90% of lymphatic filariasis. B. malayi is restricted to the South Pacific and Southeast Asia, and B. timori is restricted to several islands of Indonesia. Travelers from nonendemic areas of the world who spend brief periods of time in endemic areas are rarely infected. Global elimination has been targeted for 2020.

CLINICAL MANIFESTATIONS
The clinical manifestations of B. malayi, B. timori, and W. bancrofti infection are similar; manifestations of acute infection include transient, recurrent lymphadenitis and lymphangitis. The early signs and symptoms include episodic fever, lymphangitis of an extremity, lymphadenitis (especially the inguinal and axillary areas), headaches, and myalgias that last a few days to several weeks. These symptoms are caused by an acute inflammatory response triggered by death of adult worms. Initial damage to lymphatic vessels may remain subclinical for years. The syndrome is most frequently observed in persons 10-20 yr of age. Manifestations of chronic lymphatic filariasis occur mostly in adults 30 yr of age or older and result from anatomic and functional obstruction to lymph flow. This obstruction results in lymphedema of the legs, arms, breasts, and/or genitalia. Male genital involvement, such as hydrocele, is very common in W. bancrofti infection, but uncommon in Brugia species infection. Chronic lymphedema predisposes affected extremities to bacterial superinfections, sclerosis, and verrucous skin changes, resulting in elephantiasis, which may involve 1 or more limbs, the breasts, or genitalia. It is uncommon for children to have overt signs of chronic filariasis.

Tropical Pulmonary Eosinophilia
The presence of microfilariae in the body has no apparent pathologic consequences except in persons with tropical pulmonary eosinophilia, a syndrome of filarial etiology in which microfilariae are found in the lungs and lymph nodes but not the bloodstream. It occurs only in individuals who have lived for years in endemic areas. Men 20-30 yr of age are most likely to be affected, although the syndrome occasionally occurs in children. The presentation includes paroxysmal nocturnal cough with dyspnea, fever, weight loss, and fatigue. Rales and rhonchi are found on auscultation of the chest. The x-ray findings may occasionally be normal, but increased bronchovascular markings, discrete opacities in the middle and basal regions of the lung, or diffuse miliary lesions are usually present (Fig. 296-1). Recurrent episodes may result in interstitial fibrosis and chronic respiratory insufficiency in untreated individuals. Hepatosplenomegaly and generalized lymphadenopathy are often seen in children. The diagnosis is suggested by residence in a filarial endemic area, eosinophilia (>2,000/µL), compatible clinical symptoms, increased serum immunoglobulin E (>1,000 IU/mL), and high titer of antibodies to microfilariae. Although microfilariae may be found in sections of lung or lymph node, biopsy of these tissues is uncommon in most situations. The clinical response to diethylcarbamazine (2 mg/kg/dose tid PO for 12-21 days) is the final criterion for diagnosis; the majority of patients improve with this therapy. If symptoms recur, a second course of the anthelminthic should be administered. Patients with chronic symptoms are less likely to show improvement than those who have been ill for a short time.

DIAGNOSIS
Demonstration of microfilariae in the blood is the primary means for confirming the diagnosis of lymphatic filariasis. Because microfilariae are nocturnal in most cases, blood samples should be obtained between 10 PM and 2 AM. Anticoagulated blood is passed through a Nuclepore filter that is stained and examined microscopically for microfilariae. Adult worms or microfilariae can be identified in tissue specimens obtained at biopsy. Infection with W. bancrofti in the absence of bloodborne microfilariae may be diagnosed by detection of parasite antigen in the serum. Adult worms in lymphatic vessels can be visualized by ultrasonography.

TREATMENT
The use of antifilarial drugs in the management of acute lymphadenitis and lymphangitis is controversial. No controlled studies demonstrate that administration of drugs such as diethylcarbamazine modifies the course of acute lymphangitis. Diethylcarbamazine may be given to asymptomatic microfilaremic persons to lower the intensity of parasitemia. The drug also kills a proportion of the adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypotension, and even death may occur, especially with high microfilarial levels, the dose of diethylcarbamazine should be increased gradually (children: 1 mg/kg PO as a single dose on day 1, 1 mg/kg tid PO on day 2, 1-2 mg/kg tid PO on day 3, and 6 mg/kg/day divided tid PO on days 4-14; adults: 50 mg PO on day 1, 50 mg tid PO on day 2, 100 mg tid PO on day 3, and 6 mg/kg/day divided tid PO on days 4-14). For patients with no microfilaria in the blood, the full dose (6 mg/kg/day divided tid PO) can be given beginning on day 1. Repeat doses may be necessary to further reduce the microfilariaemia and kill lymph-dwelling adult parasites. W. bancrofti is more sensitive than B. malayi to diethylcarbamazine.

Global programs to control and ultimately eradicate lymphatic filariasis from endemic populations currently recommend a single annual dose of diethylcarbamazine (6 mg/kg PO once) in combination with albendazole (400 mg PO once) for 5 yr (mass drug administration). In coendemic areas of filariasis and onchocerciasis, mass drug applications with single-dose ivermectin (150 µg/kg PO once) and albendazole are used because of severe adverse reactions with diethylcarbamazine in onchocerciasis-infected individuals. Five years of annual mass treatment is thought to be necessary to stop transmission. Adjuvant medicines (e.g., doxycycline) that target endosymbiont bacteria (Wolbachia) in filarial parasites may accelerate eradication.

Bibliography

ONCHOCERCIASIS (ONCHOCERCA VOLVULUS)
Infection with *Onchocerca volvulus* leads to onchocerciasis or river blindness. Onchocerciasis occurs primarily in West Africa but also in Central and East Africa and is the world’s second leading infectious cause of blindness. There have been scattered foci in Central and South America, but the infection is now thought to be eliminated in the Americas with the exception of isolated populations living in the border area of Venezuela and Brazil. *O. volvulus* larvae are transmitted to humans by way of the bite of *Simulium* black flies that breed in fast-flowing streams. The larvae penetrate the skin and migrate through the connective tissue and eventually develop into adult worms that can be found tangled in fibrous tissue. Adult worms can live in the human body for up to 14 yr. Female worms produce large numbers of microfilariae that migrate through the skin, connective tissue, and eye. Most infected individuals are asymptomatic. In heavily infected subjects, clinical manifestations are a result of localized host inflammatory reactions to dead or dying microfilariae and subcutaneous adult worms surrounded by a palpable fibrous capsule. Cutaneous and ocular reactions to microfilariae produce pruritic dermatitis, punctate keratitis, corneal pannus formation, and chorioretinitis. Adult worms in subcutaneous nodules are not painful and tend to occur over bony prominences of the hip. The diagnosis can be established by obtaining snips of skin covering the scapulae, iliac crests, buttocks, or calves. The snips are immersed in saline for several hours and examined microscopically for microfilariae that have emerged into the fluid. The diagnosis can also be established by demonstrating microfilariae in the cornea or anterior chamber on slit-lamp examination or finding adult worms on a nodule biopsy specimen. Ophthalmology consultation should be obtained before treatment of eye lesions. A single dose of ivermectin (150 µg/kg PO) is the drug of choice and clears *O. volvulus* microfilariae from the skin for several months but has no effect on the adult worm. Treatment with ivermectin should be repeated every 6-12 mo until the patient is asymptomatic or has no evidence of eye infection. Adverse effects of ivermectin therapy include fever, urticaria, and pruritus, which are more frequent in individuals not born in endemic areas who acquired the infection following periods of intense exposure, such as Peace Corps volunteers. Patients with concurrent high-density microfilaraemia from loiasis may develop encephalopathy with ivermectin therapy. Treatment with ivermectin should be withheld until *Loa loa* microfilaraemia can be reduced by cyathpheresis or the use of doxycycline, which kills endosymbiont bacteria (*Wolbachia*) of *O. volvulus*. Personal protection includes avoiding areas where biting flies are numerous, wearing protective clothing, and using insect repellent. Programs of mass treatment with ivermectin have been implemented in Africa in an effort to reduce the prevalence of onchocerciasis. Although an etiologic link has not been established, epidemiologic studies have reported an association between onchocerciasis and a nodding syndrome of children living in focal areas of Uganda, Tanzania and South Sudan. The syndrome is characterized by the head dropping forward, convulsions, and periods of staring. A meta-analysis suggests an association between *O. volvulus* infection and epilepsy.

LOIASIS (LOA LOA)
Loiasis is caused by infection with the tissue nematode *Loa loa*. The parasite is transmitted to humans via diurnally biting flies (*Chrysops*) that live in the rain forests of West and Central Africa. Migration of adult worms through skin, subcutaneous tissue, and subconjunctival area can lead to transient episodes of pruritus, erythema, and localized edema known as Calabar swellings, which are nonerythematous areas of subcutaneous edema 10-20 cm in diameter typically found around joints such as the wrist or the knee (Fig. 297-1). They resolve over several days to wk and may recur at the same or different sites. Lifelong residents of *L. loa* endemic regions may have microfilaremia and eosinophilia but are often asymptomatic. In contrast, travelers to endemic regions may have a hyperreactive response to *L. loa* infection characterized by frequent recurrences of swelling, high level eosinophilia, debilitation, and serious complications such as glomerulonephritis and encephalitis. Diagnosis is usually established on clinical grounds, often assisted by the infected individual reporting a worm being seen crossing the conjunctivae. Microfilariae may be detected in blood smears collected between 10 AM and 2 PM. Adult worms should be surgically excised when possible. Diethylcarbamazine is the agent of choice for eradication of microfilariaemia, but the drug does not kill adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypertension, and even death may occur, especially with high microfilaria levels, the dose of diethylcarbamazine should be increased gradually in such cases (children: 1 mg/kg PO on day 1, 1 mg/kg tid on day 2, 1-2 mg/kg tid on day 3, 6 mg/kg in 3 doses on days 4-21; adults: 50 mg PO on day 1, 50 mg tid on day 2, 100 mg tid on day 3, 6 mg/kg in 3 doses on days 4-21). Full doses can be instituted on day 1 in persons without microfilaremia (9 mg/kg/day PO divided tid for 12 days). A single dose of ivermectin (150 µg/kg) decreases microfilarial densities in the blood in persons with high density microfilariaemia. A 3 wk course of albendazole can also be used to slowly reduce *L. loa* microfilarial levels as a result of embryotoxic effects on the adult worms. Antihistamines or corticosteroids may be used to limit allergic reactions secondary to killing of microfilariae. Personal protective measures include avoiding areas where biting flies are present, wearing protective clothing, and using insect repellents. Diethylcarbamazine (300 mg PO once weekly) prevents infection in travelers who spend prolonged periods of time in endemic areas. *L. loa* do not harbor *Wolbachia* endosymbionts, and therefore doxycycline has no effect on infection.

INFECTION WITH ANIMAL FILARIAE
The most commonly recognized zoonotic filarial infections are caused by members of the genus *Dirofilaria*. The worms are introduced into humans by the bites of mosquitoes containing third-stage larvae. The most common filarial zoonosis in the United States is *Dirofilaria tenuis*, a parasite of raccoons. In Europe, Africa, and Southeast Asia, infections are most commonly caused by the dog parasite *Dirofilaria immitis*. The dog heartworm, *Dirofilaria immitis*, is the second most commonly
encountered filarial zoonosis worldwide. Other genera, including *Dipetalonema*-like worms, *Onchocerca*, and *Brugia*, are rare causes of zoonotic filarial infections.

Animal filariae do not undergo normal development in the human host. The clinical manifestations and pathologic findings correspond to the anatomic site of infection and can be categorized into 4 major groups: subcutaneous, lung, eye, and lymphatic. Pathologic examination of affected tissue reveals a localized foreign-body reaction around a dead or dying parasite. The lesion consists of granulomas with eosinophilia, neutrophils, and tissue necrosis. *D. tenius* does not leave the subcutaneous tissues, whereas *Brugia beaveri* eventually localizes to superficial lymph nodes. Infections may be present for up to several months. *D. immitis* larvae migrate for several months in subcutaneous tissues and most frequently result in a well-circumscribed coinlike lesion in a single lobe of the lung. The chest x-ray typically reveals a solitary pulmonary nodule 1-3 cm in diameter. Definitive diagnosis and cure depend on surgical excision and identification of the nematode within the surrounding granulomatous response. *D. tenius* and *B. beaveri* infections present as painful 1-5 cm rubbery nodules in the skin of the trunk, of the extremities, and around the orbit. Patients often report having been engaged in activities predisposing to exposure to infected mosquitoes, such as working or hunting in swampy areas. Diagnosis and management is by surgical excision.

**ANGIOSTRONGYLUS CANTONENSIS**

Angiostrongylus cantonensis, the rat lungworm, is the most common cause of eosinophilic meningitis worldwide. Rats are the definitive host. Human infection follows ingestion of third-stage larvae in raw or undercooked intermediate hosts such as snails and slugs, or transport hosts such as freshwater prawns, frogs, and fish. Most cases are sporadic, but clusters have been reported, including clusters related to occupations involved in the consumption of lettuce contaminated with intermediate or transport hosts. Even though most infections have been described in Southeast Asia, the South Pacific, and Taiwan, shipboard travel of infected rats has spread the parasite to Madagascar, Africa, the Caribbean, and, most recently, Australia and North America. Larvae penetrate the vasculature of the intestinal tract and migrate to the meninges, where they usually die but induce eosinophilic aseptic meningitis. Patients present 2-35 days after ingestion of larvae with severe headache, neck pain or nuchal rigidity, hyperesthesias and paresthesias (often migrating), fatigue, fever, rash, pruritus, nausea, and vomiting. Neurologic involvement varies from asymptomatic to paresthesias, severe pain, weakness, and focal neurologic findings such as cranial nerve palsies. Symptoms can last for several weeks to months, especially headache. Coma and death from hydrocephalus occur rarely in heavy infections. Peripheral blood eosinophilia is not always present on initial examination but is seen about 5 wk after exposure, often when symptoms are improving. Cerebrospinal fluid analysis reveals pleocytosis with >10% eosinophils in more than half of patients, with mildly elevated protein, a normal glucose level, and an elevated opening pressure. Head CT or MRI is usually unremarkable. The diagnosis is established clinically with supportive travel and diet history. A sensitive and specific enzyme-linked immunosorbent assay is available on a limited basis from the Centers for Disease Control and Prevention for testing either cerebrospinal fluid or serum. Treatment is primarily supportive because the majority of infections are mild and most patients recover within 2 mo without neurologic sequelae. Analgesics should be given for headache. Careful, repeated lumbar punctures should be performed to relieve hydrocephalus. Anthelmintic drugs have not been shown to influence the outcome and may exacerbate neurologic symptoms. The use of corticosteroids may shorten the duration of persistent and severe headaches. There is a higher incidence of permanent neurologic sequelae and mortality among children than among adults. Infection can be avoided by not eating raw or undercooked crabs, prawns, or snails.

**ANGIOSTRONGYLUS COSTARICENSIS**

Angiostrongylus costaricensis is a nematode that infects several species of rodents and causes abdominal angiostrongyliasis, which has been described predominantly in Latin America and the Caribbean. The mode of transmission to humans, who are accidental hosts, is unknown. It is speculated that infectious larvae from a molluscan intermediate host, such as the slug *Vaginulus plebeius*, contaminate water or vegetation that is inadvertently consumed (chopped up in salads or on vegetation contaminated with the slug’s mucus secretions). Although this slug is not indigenous to the continental United States, it has been found on imported flowers and produce. The incubation period for abdominal angiostrongyliasis is unknown, but limited data suggest that it ranges from 2 wk to several months after ingestion of larvae. Third-stage larvae migrate from the gastrointestinal tract to the mesenteric arteries, where they mature into adults. These eggs degenerate and elicit an eosinophilic granulomatous reaction. The clinical findings of abdominal angiostrongyliasis mimic appendicitis, although the former are typically more indolent. Children can have fever, right lower quadrant pain, a tumor-like mass, abdominal rigidity, and a painful rectal examination. Most patients have leukocytosis with eosinophilia. Radiologic examination may show bowel wall edema, spasticity, or filling defects in the ileocecal region and the ascending colon. Examination of stool for ova and parasites is not useful for *A. costaricensis* but is useful for evaluating the presence of other intestinal parasites. An enzyme-linked immunosorbent assay is available for diagnosis on a limited basis from the Centers for Disease Control and Prevention, but the test has a low specificity and is known to cross react with *Toxocara*, *Strongyloides*, and *Paragonimus*. Many patients undergo laparotomy for suspected appendicitis and are found to have a mass in the terminal ileum to the ascending colon. No specific treatment is known for abdominal angiostrongyliasis. Even though the use of anthelmintic therapy has not been studied systematically, thiabendazole or diethylcarbamazine has been suggested. The prognosis is generally good. Most cases are self-limited, although surgery may be required in some patients. Cornerstones of prevention include avoidance of slugs and not ingesting raw food and water that may be contaminated with imperceptible slugs or slime from slugs. Rat control is also important in preventing the spread of infection.

**DRACUNCULIASIS (DRACUNCULUS MEDINENSIS)**

Dracunculiasis is caused by the guinea worm, *Dracunculus medinensis*. The World Health Organization has targeted dracunculiasis for eradication. As of 2012, the transmission of the infection was confined to Chad, Ethiopia, Mali, and South Sudan. Humans become infected by drinking contaminated stagnant water that contains immature forms of the parasite in the gut of tiny crustaceans (copepods or water fleas). Larvae are released in the stomach, penetrate the mucosa, mature, and mate. Approximately 1 yr later, the adult female worm (1-2 mm in diameter and up to 1 m long) migrates and partially emerges through the human host skin, usually of the legs. Thousands of immature larvae are released when the affected body part is immersed in the water. The cycle is completed when larval forms are ingested by the crustaceans. Infected humans have no symptoms until the worm reaches the subcutaneous tissue, causing a stinging papule that may be accompanied by urticaria, nausea, vomiting, diarrhea, and dyspnea. The lesion vesiculates, ruptures, and forms a painful ulcer in which a portion of the worm is visible. Diagnosis is established clinically. Larvae can be identified by microscopic examination of the discharge fluid. Metronidazole (25 mg/kg/day PO divided into 3 doses for 10 days; maximum dose: 750 mg) decreases local inflammation. Although the drug does not kill the worm, it facilitates its removal. The worm must be physically removed by rolling the slowly emerging 1 m long parasite onto a thin stick over a week. Topical corticosteroids shorten the time to complete healing while topical antibiotics decrease the risk of secondary bacterial infection. Dracunculiasis can be prevented by boiling or chlorinating drinking water or passing the water through a cloth sieve before consumption. Eradication is dependent on behavior modification and education.

**GNATHOSTOMA SPINIGERUM**

*Gnathostoma spinigerum* is a dog and cat nematode endemic to Southeast Asia, Japan, China, Bangladesh, and India, but has been identified...
in Mexico and parts of South America. Infection is acquired by ingesting intermediate hosts containing larvae of the parasite such as raw or undercooked freshwater fish, chickens, pigs, snails, or frogs. Penetration of the skin by larval forms and prenatal transmission has also been described. Nonspecific signs and symptoms such as generalized malaise, fever, urticaria, anorexia, nausea, vomiting, diarrhea, and epigastric pain develop 24-48 hr after ingestion of G. spinigerum. Ingested larvae penetrate the gastric wall and migrate through soft tissue for up to 10 yr. Moderate to severe eosinophilia can develop. Cutaneous gnathostomiasis manifests as intermittent episodes of localized, migratory nonpitting edema associated with pain, pruritus, or erythema. Central nervous system involvement in gnathostomiasis is suggested by focal neurologic findings, initially neuralgia followed within a few days by paralysis or changes in mental status. Multiple cranial nerves may be involved, and the cerebrospinal fluid may be xanthochromic but typically shows an eosinophilic pleocytosis. Diagnosis of gnathostomiasis is based on clinical presentation and epidemiologic background. Brain and spinal cord lesions may be seen on CT or MRI. Serologic testing varies in sensitivity and specificity and is available through the Centers for Disease Control and Prevention. There is no well-documented effective chemotherapy, although albendazole (400 mg PO bid for 21 days) as first-line therapy or ivermectin (200 µg/kg for 2 days) as an alternative is recommended without or with surgical removal. Multiple courses may be needed. Corticosteroids have been used to relieve focal neurologic deficits. Surgical resection of the Gnathostoma is the major mode of therapy and the treatment of choice. Blind surgical resection of subcutaneous areas of diffuse swelling is not recommended because the worm can rarely be located. Prevention through the avoidance of ingestion of poorly cooked or raw fish, poultry, or pork should be emphasized for individuals living in or visiting endemic areas.

Bibliography

**Onchocerciasis (Onchocerca Volvulus)**

**Loiasis (Loa Loa)**

**Infection with Animal Filariae**

**Angiostrongylus Cantonensis**

**Angiostrongylus Costaricensis**

**Dracunculiasis (Dracunculus Medinensis)**

**Gnathostoma Spinigerum**
Popular household pets. Young children are at highest risk because of their unsanitary play habits and tendency to place fingers in the mouth. Other behavioral risk factors include pica, contact with puppy litters, and institutionalization. In North America, the highest prevalences of infection are in the southeastern United States and Puerto Rico, particularly among socially disadvantaged African-American and Hispanic children. In the United States, serosurveys show that 4.6–7.3% of children are infected. Assuming an unrestrained and untreated dog population, toxocariasis is prevalent in settings where other geohelminth infections, such as ascariasis, trichiuriasis, and hookworm infections, are common.

**PATHOGENESIS**

*T. canis* larvae secrete large amounts of immunogenic glycosylated proteins. These antigens induce immune responses that lead to eosinophilia and polyclonal and antigen-specific immunoglobulin E production. The characteristic histopathologic lesions are granulomas containing eosinophils, multinucleated giant cells (histiocytes), and collagen. Granulomas are typically found in the liver but may also occur in the lungs, central nervous system, and ocular tissues. Clinical manifestations reflect the intensity and chronicity of infection, anatomic localization of larvae, and host granulomatous responses.

**CLINICAL MANIFESTATIONS**

There are 3 major clinical syndromes associated with human toxocariasis: VLM, ocular larva migrans (OLM), and covert toxocariasis (Table 298-1). The classic presentation of VLM includes eosinophilia, fever, and hepatomegaly, and occurs most commonly in toddlers with a history of pica and exposure to puppies. The findings include fever, cough, wheezing, bronchopneumonia, anemia, hepatomegaly, leukocytosis, eosinophilia, and positive *Toxocara* serology. Cutaneous manifestations such as pruritus, eczema, and urticaria can be present. OLM tends to occur in older children without signs or symptoms of VLM. Presenting symptoms include unilateral visual loss, eye pain, white pupil, or strabismus that develops over a period of weeks. Granulomas occur on the posterior pole of the retina and may be mistaken for retinoblastoma. Serologic testing for *Toxocara* has allowed the identification of individuals with less obvious or covert symptoms of infection. These children may have nonspecific complaints that do not constitute a recognizable syndrome. Common findings include hepatomegaly, abdominal pain, cough, sleep disturbance, failure to thrive, and headache with elevated *Toxocara* antibody titers. Eosinophilia may be present in only 50–75% of cases. The prevalence of positive *Toxocara* serology in the general population supports the notion that most children with *T. canis* infection are asymptomatic and will not develop overt clinical sequelae over time. A correlation between positive *Toxocara* serology and allergic asthma has also been described.

**DIAGNOSIS**

A presumptive diagnosis can be established in a young child with eosinophilia (>20%), leukocytosis, hepatomegaly, fevers, wheezing, and a history of geophagia and exposure to puppies or unrestrained dogs. Supportive laboratory findings include hypergammaglobulinemia and elevated isohemagglutinin titers to A and B blood group antigens. Most patients with VLM have an absolute eosinophil count of >500/µL. Eosinophilia is less common in subjects with OLM. Biopsy confirms the diagnosis. When biopsies cannot be obtained, an enzyme-linked immunosorbent assay using excretory-secretory proteins harvested from *T. canis* larvae maintained in vitro is the standard serologic test used to confirm toxocariasis. A titer of 1:32 is associated with a sensitivity of approximately 78% and a specificity of approximately 92%. The sensitivity for OLM is significantly less. The diagnosis of OLM can be established in patients with typical clinical findings of a retinal or peripheral pole granuloma or endophthalmitis with elevated antibody titers. Vitreous and aqueous humor fluid anti-*Toxocara* titers are usually greater than serum titers. The diagnosis of covert toxocariasis should be considered in individuals with chronic weakness, abdominal pain, or allergic signs with eosinophilia and increased immunoglobulin E. In temperate regions of the world, nonparasitic causes of eosinophilia that should be considered in the differential diagnosis include allergies,
drug hypersensitivity, lymphoma, vasculitis, and the idiopathic hypereosinophilic syndrome (see Chapter 129).

**TREATMENT**

Most cases do not require treatment because signs and symptoms are mild and subside over a period of weeks to months. Several anthelminthic drugs have been used for symptomatic cases, often with adjunctive corticosteroids to limit inflammatory responses that presumably result from release of *Toxocara* antigens by dying parasites. Albendazole (400 mg PO bid for 5 days for all ages) has demonstrated efficacy in both children and adults. Mebendazole (100-200 PO mg bid for 5 days for all ages) is also useful. Anthelmintic treatment of central nervous system and ocular disease should be extended (3-4 wk). Even though there are no clinical trials regarding therapy of OLM, a course of oral corticosteroids such as prednisone (1 mg/kg/day PO for 2-4 wk) has been recommended to suppress local inflammation while treatment with anthelmintic agents is initiated.

**PREVENTION**

Transmission can be minimized by public health measures that prevent dog feces from contaminating the environment. These include keeping dogs on leashes and excluding pets from playgrounds and sandboxes that toddlers use. Children should be discouraged from putting dirty fingers in their mouth and eating dirt. Vinyl covering of sandboxes reduces the viability of *T. canis* eggs. Widespread veterinary use of broad-spectrum anthelmintics effective against *Toxocara* may lead to a decline in parasite transmission to humans.

Chapter 299

Trichinellosis (Trichinella spiralis)
Arlene E. Dent and James W. Kazura

ETIOLOGY
Human trichinellosis (also called trichinosis) is caused by consumption of meat containing encysted larvae of Trichinella spiralis, a tissue-dwelling nematode with a worldwide distribution. After ingestion of raw or inadequately cooked meat from pigs (or other commercial meat sources such as horses) containing viable Trichinella larvae, the organisms are released from the cyst by acid-pepsin digestion of the cyst walls in the stomach and then pass into the small intestine. The larvae invade the small intestine columnar epithelium at the villi base and develop into adult worms. The adult female worm produces about 500 larvae over 2 wk and is then expelled in the feces. The larvae enter the bloodstream and seed striated muscle by burrowing into individual muscle fibers. Over a period of 3 wk, they coil as they increase about 10 times in length and become capable of infecting a new host if ingested. The larvae eventually become encysted and can remain viable for years. Sylvatic Trichinella spp. (T. brivoti, T. nativa, T. pseudospiralis, and T. murrelli) present in traditional native foods such as walrus meat and game meat may also cause disease similar to that caused by T. spiralis.

EPIDEMIOLOGY
Despite public health efforts to control trichinellosis by eliminating the practice of feeding garbage to domestic swine, epidemics and isolated cases of Trichinella spp. infection continue to be a health problem in many areas of the world. It is most common in Asia, Latin America, and Central Europe. Swine fed with garbage may become infected when given uncooked trichinous scraps, usually pig meat, or when the carcasses of infected wild animals such as rats are eaten. Prevalence rates of T. spiralis in domestic swine range from 0.001% in the United States to ≥25% in China. The resurgence of this disease can be attributed to translocations of animal populations, human travel, and export of food as well as ingestion of sylvatic Trichinella (T. brivoti, T. nativa, T. pseudospiralis, and T. murrelli) through game meat. In the United States from 1997 to 2001, wild game meat (especially bear meat) was the most common source of infection. Most outbreaks occur from the consumption of T. spiralis–infected pork (or horse meat in areas of the world where horse is eaten) obtained from a single source.

PATHOGENESIS
During the 1st 2-3 wk after infection, pathologic reactions to infection are limited to the gastrointestinal tract and include a mild, partial villous atrophy with an inflammatory infiltrate of neutrophils, eosinophils, lymphocytes, and macrophages in the mucosa and submucosa. Larvae are released by female worms and disseminate over the next several weeks. Skeletal muscle fibers show the most striking changes with edema and basophilic degeneration. The muscle fiber may contain the typical coiled worm, the cyst wall derived from the host cell, and the surrounding lymphocytic and eosinophilic infiltrate.

CLINICAL MANIFESTATIONS
The development of symptoms depends on the number of viable larvae ingested. Most infections are asymptomatic or mild, and children often show milder symptoms than adults who consumed the same amount of infected meat. Watery diarrhea is the most common symptom corresponding to maturation of the adult worms in the gastrointestinal tract, which occurs during the 1st 1-2 wk after ingestion. Patients may also complain of abdominal discomfort and vomiting. Fulminant
enteritis may develop in individuals with extremely high worm burdens. The classic symptoms of facial and periorbital edema, fever, weakness, malaise, and myalgia peak approximately 2-3 wk after the infected meat is ingested as the larvae migrate and then encyst in the muscle. Headache, cough, dyspnea, dysphagia, subconjunctival and splinter hemorrhages, and a macular or petechial rash may occur. Patients with high-intensity infection may die from myocarditis, encephalitis, or pneumonia. In symptomatic patients, eosinophilia is common and may be dramatic.

**DIAGNOSIS**

The Centers for Disease Control and Prevention diagnostic criteria for trichinellosis require positive serology or muscle biopsy for *Trichinella* with 1 or more compatible clinical symptoms (eosinophilia, fever, myalgia, facial or periorbital edema). To declare a discrete outbreak, at least 1 person must have positive serology or muscle biopsy. Antibodies to *Trichinella* are detectable approximately 3 wk after infection. Severe muscle involvement results in elevated serum creatine phosphokinase and lactic dehydrogenase levels. Muscle biopsy is not usually necessary, but if needed, a sample should be obtained from a tender swollen muscle. A history of eating undercooked meat supports the diagnosis. The cysts may calcify and be visible by radiograph.

**TREATMENT**

Recommended treatment of trichinellosis diagnosed at the gastrointestinal phase is albendazole (400 mg PO bid for 8-10 days for all ages) to eradicate the adult worms if a patient has ingested contaminated meat within the previous 1 wk. An alternative regimen is mebendazole (200-400 mg PO tid for 3 days followed by 400-500 mg tid for 10 days). There is no consensus for treatment of muscle-stage trichinellosis. Corticosteroids may be used, although evidence for efficacy is anecdotal.

**PREVENTION**

*Trichinella* larvae can be killed by cooking meat (≥55°C [131°F]) until there is no trace of pink fluid or flesh, or by storage in a freezer (−15°C [5°F]) for ≥3 wk. Freezing to kill larvae should only be applied to pork meat, as larvae in horse, wild boar, or game meat can remain viable even after 4 wk of freezing. Smoking, salting, and drying meat are unreliable methods of killing *Trichinella*. Strict adherence to public health measures, including garbage feeding regulations, stringent rodent control, prevention of exposure of pigs and other livestock to animal carcasses; constructing barriers between livestock, wild animals, and domestic pets; and proper handling of wild animal carcasses by hunters, can reduce infection with *Trichinella*. Current meat inspection for trichinellosis is by direct digestion and visualization of encysted larvae in meat samples. Serologic testing does not have a role in meat inspection.

Schistosomiasis (Schistosoma)

Charles H. King and Amaya L. Bustinduy

The term *schistosomiasis* (bilharzia) encompasses the acute and chronic inflammatory disorders caused by human infection with *Schistosoma* spp. parasites. Disease is related to both the systemic and focal effects of schistosome infection and its consequent host immune responses triggered by parasite eggs deposited in the tissues. For the affected individuals, this frequently manifests as disabling chronic morbidity.

**ETIOLOGY**

*Schistosoma* organisms are the trematodes, or flukes, that parasitize the bloodstream. Five schistosome species infect humans: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. intercalatum*, and *S. mekongi*. Humans are infected through contact with water contaminated with cercariae, the free-living infective stage of the parasite. These motile, forked-tail organisms emerge from infected snails and are capable of penetrating intact human skin. As they reach maturity, adult worms migrate to specific anatomic sites characteristic of each schistosome species: *S. haematobium* adults are found in the perivesical and periureteral venous plexus, *S. mansoni* in the inferior mesenteric veins, and *S. japonicum* in the superior mesenteric veins. *S. intercalatum* and *S. mekongi* are usually found in the mesenteric vessels. Adult schistosome worms (1-2 cm long) are clearly adapted for an intravascular existence. The female accompanies the male in a groove formed by the lateral edges of its body. On fertilization, female worms begin oviposition in the small venous tributaries. The eggs of the 3 main schistosome species have characteristic morphologic features: *S. haematobium* has a terminal spine, *S. mansoni* has a lateral spine, and *S. japonicum* has a smaller size with a short, curved spine (Fig. 300-1). Parasite eggs provoke a significant granulomatous inflammatory response, which allows them to ulcerate through host tissues to reach the lumen of the urinary tract or intestines. They are carried to the outside environment in urine or feces (depending on the species), where they will hatch if deposited in freshwater. Motile miracidia emerge, infect specific freshwater snail intermediate hosts, and divide asexually. After 4-12 wk, the infective cercariae are released by the snails into the contaminated water.

**EPIDEMIOLOGY**

Schistosomiasis infects more than 207 million people worldwide, primarily children and young adults. Prevalence is increasing in many areas as population density increases and new irrigation projects provide broader habitats for vector snails. Humans are the main definitive hosts for the 5 clinically important species of schistosomes, although *S. japonicum* is also a zoonosis, infecting animals such as dogs, rats, pigs, and cattle. *S. haematobium* is prevalent in Africa and the Middle East; *S. mansoni* is prevalent in Africa, the Middle East, the Caribbean, and South America; and *S. japonicum* is prevalent in China, the Philippines, and Indonesia, with some sporadic foci in parts of Southeast Asia. The other 2 species are less prevalent. *S. intercalatum*...
to other organs, most commonly the liver and less often the lungs and central nervous system. The host response to these eggs involves local as well as systemic manifestations. The cell-mediated immune response leads to granulomas composed of lymphocytes, macrophages, and eosinophils that surround the trapped eggs and add significantly to the degree of tissue destruction. Granuloma formation in the bladder wall and at the ureterovesical junction results in the major disease manifestations of schistosomiasis haematobia: hematuria, dysuria, and obstructive uropathy. Intestinal as well as hepatic granulomas underlie the pathologic sequelae of the other schistosome infections: ulcerations and fibrosis of intestinal wall, hepatosplenomegaly, and portal hypertension due to presinusoidal obstruction of blood flow. In terms of systemic disease, antischistosome inflammation increases circulating levels of proinflammatory cytokines such as tumor necrosis factor-α and interleukin-6, associated with elevated levels of C-reactive protein. These responses are associated with hepcidin-mediated inhibition of iron uptake and use, leading to anemia of chronic inflammation. Schistosomiasis-related undernutrition may be the result of similar pathways of chronic inflammation. Acquired partial protective immunity against schistosomiasis has been demonstrated in some animal species and may occur in humans.

**CLINICAL MANIFESTATIONS**

Most chronically infected individuals experience mild symptoms and may not seek medical attention; the more severe symptoms of schistosomiasis occur mainly in those who are heavily infected or who have been infected over longer periods of time. In addition to organ-specific morbidities, infected patients frequently demonstrate anemia, chronic pain, diarrhea, exercise intolerance, and chronic undernutrition manifesting as growth stunting. Cercarial penetration of human skin may result in a papular pruritic rash known as schistosomal dermatitis or swimmer’s itch. It is more pronounced in previously exposed individuals and is characterized by edema and intense cellular infiltrates in the dermis and epidermis. Acute schistosomiasis, Katayama syndrome, may occur, particularly in heavily infected individuals 4–8 wk after exposure; this is a serum sickness–like syndrome manifested by the acute onset of fever, cough, chills, sweating, abdominal pain, lymphadenopathy, hepatosplenomegaly, and eosinophilia. Acute schistosomiasis most commonly presents in first-time visitors to endemic areas who experience primary infection at an older age.

Symptomatic children with chronic schistosomiasis haematobia usually complain of frequency, dysuria, and hematuria. Urine examination shows erythrocytes, parasite eggs, and occasional eosinophilia. In endemic areas, moderate to severe pathologic lesions have been demonstrated in the urinary tract of >20% of infected children. The extent of disease correlates with the intensity of infection, but significant morbidity can occur even in lightly infected children. The advanced stages of schistosomiasis haematobia are associated with chronic renal failure, secondary infections, and cancer of the bladder.

An important complication of *S. haematobium* infection is female genital schistosomiasis. Eggs migrate from the vesical plexus to lodge in the female genital tract where they induce a granulomatous inflammatory response that can manifest as contact bleeding, pain, and eventual infertility. Symptoms start as early as 10 yr of age with an apparent 3–4-fold greater risk of HIV transmission. Pathognomonic lesions can be visualized in the cervix by photocolposcopy.

Children with chronic schistosomiasis *mansonii, japonica, intercalatum,* or *mekongi* may have intestinal symptoms; colicky abdominal pain and bloody diarrhea are the most common. However, the intestinal phase may remain subclinical, and the late syndrome of hepatosplenomegaly, portal hypertension, ascites, and hematemia may then be the first clinical presentation. Liver disease is caused by granuloma formation and subsequent fibrosis; no appreciable liver cell injury occurs, and hepatic function may be preserved for a long time. Schistosome eggs may escape into the lungs, causing pulmonary hypertension and cor pulmonale. *S. japonicum* worms may migrate to the brain vasculature and produce localized lesions that cause seizures. Transverse myelitis, spinal compression, and other central nervous system involvement (meningoencephalitis) are rare but well known

is found in West and Central Africa, and *S. mekongi* is found only along the upper Mekong River in the Far East.

Transmission depends on disposal of excreta, the presence of specific intermediate snail hosts, and the patterns of water contact and social habits of the population (Fig. 300-2). The distribution of infection in endemic areas shows that prevalence increases with age, to a peak at 10–20 yr of age. Exposure to infected water starts early in life for children living in endemic areas. Passive water contact by infants (accompanying mothers in their daily household activities) evolves to more active water contact as school age children pursue recreational activities such as swimming and wading.

Measuring intensity of infection (by quantitative egg count in urine or feces) demonstrates that the heaviest worm loads are found in school-age and adolescent children. Therefore, schistosomiasis is most prevalent and most severe in children and young adults, who are at maximal risk for suffering from its acute and chronic sequelae.

**PATHOGENESIS**

Both the early and late manifestations of schistosomiasis are immunologically mediated. Acute schistosomiasis, known as snail fever or Katayama syndrome, is a febrile illness that represents an immune complex disease associated with early infection and oviposition. The major pathology of infection occurs later, with chronic schistosomiasis, in which retention of eggs in the host tissues is associated with chronic granulomatus injury. Eggs may be trapped at sites of deposition (urinary bladder, ureters, intestine) or be carried by the bloodstream

complications in children or young adults with either acute or chronic 
*S. haematobium* or *S. mansoni* infection.

Although end-organ scarring is pathognomonic, affected children 
may also have persistent long-term systemic effects of infection, 
including poor growth, anemia, decreased aerobic capacity, and cogni 
tive impairment.

**DIAGNOSIS**

Schistosome eggs are found in the excreta of infected individuals; 
quantitative methods should be used to provide an indication of the 
burden of infection. For diagnosis of schistosomiasis haematobia, a 
volume of 10 mL of urine should be collected around midday, which 
is the time of maximal egg excretion, and filtered for microscopic 
examination. Stool examination by the Kato-Katz thick smear proce 
dure and detection of parasite antigen in patient serum or urine are 
the methods of choice for diagnosis and quantification of other schisto 
some infections.

**TREATMENT**

Treatment of children with schistosomiasis should be based on an 
appreciation of the intensity of infection and the extent of disease. The 
recommended treatment for schistosomiasis is praziquantel (40 mg/ 
kg/day divided bid PO for 1 day for schistosomiasis haematobia, 
mansoni, and intercalatum; 60 mg/kg/day divided tid PO for 1 day for 
schistosomiasis japonica and mekongi). For *S. mansoni*, oxamniquine 
has been effective in some areas where praziquantel has been less effective.

**PREVENTION**

Transmission in endemic areas may be decreased by reducing the 
parasite load in the human population. The availability of oral, single 
dose, effective chemotherapeutic agents may help achieve this goal. 
When added to national control drug-based programs, other measures 
such as improved sanitation, focal application of molluscicidals, and 
animal vaccination may prove useful in breaking the cycle of transmis 
sion. Ultimately, control of schistosomiasis is closely linked to eco 
nomic and social development.

Bibliography

Several different trematodes, or flukes, can parasitize humans and cause disease. Flukes are endemic worldwide but are more prevalent in the less-developed parts of the world. They include *Schistosoma*, or the blood flukes (see Chapter 300), as well as fluke species that cause infection in the human biliary tree, lung tissue, and intestinal tract. These latter trematodes are characterized by complex life cycles (Fig. 301-1). Sexual reproduction of adult worms in the definitive host produces eggs that are passed in the stool. Larvae, called *miracidia*, develop in freshwater. These, in turn, infect certain species of mollusks (aquatic snails or clams), in which asexual multiplication by parasite larvae produces *cercariae*. Cercariae then seek a second intermediate host, such as an insect, crustacean, or fish, or attach to vegetation to produce infectious *metacercariae*. Humans acquire liver, lung, and intestinal fluke infections by eating uncooked, lightly cooked, pickled, or smoked foods containing these infectious parasite cysts. The “alternation of generations” requires that flukes parasitize more than 1 host (often 3) to complete their life cycle. Because parasitic flukes are dependent on these nonhuman species for transmission, the distribution of human fluke infection closely matches the ecologic range of the flukes’ intermediate hosts.

**LIVER FLUKES**

Fascioliasis (*Fasciola Hepatica*)

*Fasciola hepatica*, the sheep liver fluke, infects cattle, other ungulates, and occasionally humans. This infection affects approximately 17 million people worldwide and has been reported in many different
parts of the world, particularly South America, Europe, Africa, China, Australia, and Cuba. Although *F. hepatica* is enzootic in North America, reported cases are extremely rare. Humans are infected by ingestion of metacercariae attached to vegetation, especially wild watercress, lettuce, and alfalfa. In the duodenum, the parasites excyst and penetrate the intestinal wall, liver capsule, and parenchyma. They wander for a few weeks before entering the bile ducts, where they mature. Adult *F. hepatica* (1-2.5 cm) commence oviposition approximately 12 wk after infection; the eggs are large (75-140 mm) and operculated. They pass to the intestines with bile and exit the body in the feces (see Fig. 301-1). On reaching freshwater, the eggs mature and hatch into miracidia, which infect specific snail intermediate hosts to multiply into many cercariae. These then emerge from infected snails and encyst on aquatic grasses and plants.

Clinical manifestations usually occur either during the liver migratory phase of the parasites or after their arrival at their final habitat in upper bile ducts. Fever, right upper quadrant pain, and hepatosplenomegaly characterize the first phase of illness. Peripheral blood eosinophilia is usually marked. As the worms enter bile ducts, most of the acute symptoms subside. On rare occasions, patients may suffer from obstructive jaundice or biliary cirrhosis, with signs of cholestasis, ascending cholangitis, cholelithiasis and jaundice with elevation in liver enzymes, direct bilirubin, and \( \gamma \)-glutamyl transpeptidase. *F. hepatica* infection is diagnosed by identifying the characteristic eggs in fecal smears or duodenal aspirates. Diagnosis can be suggested by positive serology and imaging that reveals acute hypodense liver lesions that change over time. Presentation can be dramatic in children, with features including generalized edema, hepatic cirrhosis with esophageal varices, and, in severe cases, death from generalized organ failure.

The recommended treatment of fascioliasis is triclabendazole (10 mg/kg once or twice PO) or bithionol (30-50 mg/kg once daily PO on alternate days for a total of 10-15 doses). In the United States, bithionol is available from the Centers for Disease Control and Prevention (telephone: 404-639-3670).

**Clonorchiasis (Clonorchis Sinensis)**

Infection of bile passages with *Clonorchis sinensis*, the Chinese or oriental liver fluke, is endemic in China, other parts of East Asia, and Japan, affecting more than 35 million people. Humans acquire infection by ingestion of raw or inadequately cooked freshwater fish carrying the encysted metacercariae of the parasite under their scales or skin. Metacercariae excyst in the duodenum and pass through the ampulla of Vater to the common bile duct and bile capillaries, where they mature into hermaphroditic adult worms (3-15 mm). *C. sinensis* worms deposit small operculated eggs (14-30 mm), which are discharged by way of the bile duct to the intestine and feces (see Fig. 301-1). The eggs mature and hatch outside the body, releasing motile miracidia into local freshwater streams, rivers, or ponds. If these are taken up by the appropriate snails, they develop into cercariae, which are in turn released from the snail to encyst under the skin or scales of freshwater fish.

Most individuals with *C. sinensis* infection, particularly those with few organisms, are minimally symptomatic. In heavily infected individuals, who tend to be older (>30 yr of age), localized obstruction of a bile duct results from repeated local trauma and inflammation. In these cases, cholangitis and cholangiohepatitis may lead to liver enlargement and jaundice. In Hong Kong, Korea, and other parts of Asia, cholangiocarcinoma is associated with chronic *C. sinensis* infection. Clonorchiasis is diagnosed by examination of feces or duodenal aspirates for the parasite eggs. The recommended treatment of clonorchiasis is praziquantel (75 mg/kg/day divided tid PO for 2 days). An alternative, used in adults, is albendazole (10 mg/kg once daily PO for 7 days).

**Opisthorchiasis (Opisthorchis Spp.)**

Infections with species of *Opisthorchis* are clinically similar to those caused by *C. sinensis*. *Opisthorchis felineus* and *Opisthorchis viverrini* are liver flukes of cats and dogs that infect humans through ingestion of metacercariae in freshwater fish. Infection with *O. felineus* is endemic in Eastern Europe and Southeast Asia, and *O. viverrini* is found mainly in Thailand, affecting an estimated 10 million people. Most individuals are minimally symptomatic; liver enlargement, relapsing cholangitis, and jaundice may occur in heavily infected individuals. Diagnosis is based on recovering eggs from stools or duodenal aspirates. The recommended treatment of opisthorchiasis is praziquantel (75 mg/kg/day divided tid PO for 2 days).

**LUNG FLUKES**

**Paragonimiasis (Paragonimus Spp.)**

Human infection by the lung fluke *Paragonimus westermani*, and less frequently other species of *Paragonimus*, occurs throughout the Far East, in localized areas of West Africa, and in several parts of Central and South America, affecting approximately 20 million people. The highest incidence of paragonimiasis occurs in older children and adolescents 11-15 yr of age. Although *P. westermani* is found in many carnivores, human cases are relatively rare and seem to be associated with specific dietary habits, such as eating raw freshwater crayfish or crabs. These crustaceans contain the infective metacercariae in their tissues. After ingestion, the metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate to their final habitat in the lungs. Adult worms (5-10 mm) encapsulate within the lung parenchyma and deposit brown operculated eggs (60-100 mm), which pass into the bronchioles and are expectorated by coughing (see Fig. 301-1). Ova can be detected in the sputum of infected individuals or in their feces. If eggs reach freshwater, they hatch and undergo asexual multiplication in specific snails. The cercariae encyst in the muscles and viscera of crayfish and freshwater crabs.

Most individuals infected with *P. westermani* harbor low or moderate worm loads and are minimally symptomatic. The clinical manifestations include cough, production of rust-colored sputum, and hemoptysis (mimicking tuberculosis), which is the principal manifestation and occurs in 98% of symptomatic children. There are no characteristic physical findings, but laboratory examination usually demonstrates marked eosinophilia. Chest x-rays often reveal small patchy infiltrates or radiolucencies in the middle lung fields; however, radiographs may appear normal in one-fifth of infected individuals. In rare circumstances, lung abscess, pleural or pericardial effusion, or bronchiectasis may develop. Extrapulmonary localization of *P. wester-

ETIOLOGY

The beef tapeworm (Taenia saginata), the pork tapeworm (T. solium), and the Asian tapeworm (Taenia asiatica) are long worms (4-10 m) named for their intermediate hosts (T. saginata, T. solium) or geographic distribution (T. asiatica; larval host is the pig). The adult worms are found only in the human intestine. Like the adult stage of all tapeworms, their body is a series of hundreds or thousands of flattened segments (proglottids) with an anterior attachment organ (scolex) that anchors the parasite to the bowel wall. New segments arise from the distal aspect of the scolex with progressively more mature segments attached distally. The gravid terminal segments contain 50,000–100,000 eggs, and the eggs or even detached intact proglottids pass out of the child via the anus (with or separate from defecation). These tapeworms differ most significantly in that the intermediate stage of the pork tapeworm (cysticercus) can also infect humans and cause significant morbidity (see Chapter 303), whereas the larval stage of T. saginata does not cause human disease. T. asiatica is similar to and often confused with the beef tapeworm.

Epidemiology

The pork and beef tapeworms are distributed worldwide, with the highest risk for infection in Central America, Africa, India, Southeast Asia, and China where the relevant intermediate host is raised domestically. The prevalence in adults may not reflect the prevalence in young children, because cultural practices may dictate how well meat is cooked and how much is served to children.

Pathogenesis

When children ingest raw or undercooked meat containing larval cysts, gastric acid and bile facilitate release of immature scolecis that attach to the lumen of the small intestine. The parasite grows, adding new segments at the base of the scolex. The terminal segments mature and after 2–3 mo produce eggs that are released in stool. The surface of proglottids serves as an absorptive organ to “steal” nutritional elements from the child’s small bowel for use by the parasite. There is sometimes a transient eosinophilia prior to the parasite maturing enough to release eggs.

Clinical Manifestations

Nonspecific abdominal symptoms have been reported with beef and pork tapeworm infections, but the most bothersome symptom is the psychologic distress caused by seeing proglottids in the stool or undergarments. The released segments of the worms are motile (especially those of T. saginata) and sometimes lead to anal pruritus. The adult beef and pork tapeworms are only rarely associated with other symptoms.

Diagnosis

Identification of the infecting tapeworm species facilitates understanding of risk for invasive disease. Carriers of adult pork tapeworms are at increased risk for transmitting eggs with the pathogenic intermediate stage (cysticercus) to themselves or others, whereas children infected with the beef tapeworm or T. asiatica are a risk only to livestock. Because proglottids are generally passed intact, visual examination for gravid proglottids in the stool is a sensitive test; these segments may be used to identify species. Eggs, by contrast, are often absent from stool and cannot distinguish between T. saginata and T. solium (Fig. 302-1). If the parasite is completely expelled, the scolex of each species is diagnostic. The scolex of T. solium has only a set of 4 anteriorly oriented suckers, whereas T. solium is armed with a double row of hooks in addition to suckers. The proglottids of T. saginata have more than 20 branches from a central uterine structure, and those of T. solium have 10 or fewer. Expelled proglottid segments are usually about 0.5×1-2×0.1 cm in size. Molecular methods can distinguish T. saginata from T. asiatica. Antigen detection tests are increasingly available.

Part XVII

**Differential Diagnosis**

Anal pruritus may mimic symptoms of pinworm (*Enterobius vermicularis*) infection. *Diphyllobothrium latum* and *Ascaris lumbricoides* (a long round worm) may be mistaken for *T. saginata* or *T. solium* in stools.

**TREATMENT**

Infections with all adult tapeworms respond to praziquantel (25 mg/kg PO once). When available, an alternative treatment for taeniasis is niclosamide (50 mg/kg PO once for children, 2 g PO once for adults). Nitzoxanide is sometimes effective as well. The parasite is usually expelled on the day of administration. Treatment with electrolyte-polyethylene glycol bowel preparations can increase the yield of passage of scolices.

**PREVENTION**

Prolonged freezing or thorough cooking of beef and pork kills the larval cystic forms of the parasite. Appropriate human sanitation can interrupt transmission by preventing infection in livestock.

**Diphyllobothriasis (Diphyllobothrium Species)**

**Etiology**

The fish tapeworms of the genus *Diphyllobothrium* are the longest human tapeworms, reaching more than 10 meters in length, and have an anatomic organization similar to that of other adult cestodes. An elongated scolex equipped with slits (bothria) along each side but no suckers or hooks is surrounded by thousands of segments looped in the small bowel. Gravid terminal proglottids detach periodically but tend to disintegrate before expulsion, thus releasing eggs rather than intact worm segments in the feces. In contrast to taeniids, the life cycle of *Diphyllobothrium* species requires 2 intermediate hosts. Small fresh water crustaceans (copepods) take up the larvae that hatch from parasite eggs. The parasite passes up the food chain as small fish eat the copepods and are in turn eaten by larger fish. In this way, the juvenile parasite becomes concentrated in pike, walleye, perch, burbot, and perhaps salmon associated with aquaculture of this species. Consumption of raw or undercooked fish leads to human infection with adult fish tapeworms.

**Epidemiology**

The fish tapeworm is most prevalent in the temperate climates of Europe, North America, and Asia but may be found along the Pacific coast of South America and in Africa. In North America, the prevalence is highest in Alaska, Canada, and northern areas of continental United States. The tapeworm is found in fish from those areas that are then taken to market. Persons who prepare raw fish for home or commercial use or who sample fish before cooking are particularly at risk for infection.

**Pathogenesis**

The adult worm of *D. latum* (found in northern Europe) has high affinity receptors and efficiently scavenges vitamin B₁₂ for its own use in the constant production of large numbers of segments and as many as 1 million eggs per day. As a result, diphyllobothriasis causes megaloblastic anemia in 2-9% of infections. Interestingly, other *Diphyllobothrium* species do not out-compete the host for vitamin B₁₂. Children with other causes of vitamin B₁₂ or folate deficiency, such as chronic infectious diarrhea, celiac disease, or congenital malabsorption, are more likely to develop symptomatic infection.

**Clinical Manifestations**

Infection is largely asymptomatic. Segments may be noted in stool. Those who develop vitamin B₁₂ or folate deficiency present with megaloblastic anemia with leukopenia, thrombocytopenia, glossitis, and/or signs of spinal cord posterior column dysfunction (loss of vibratory sense, proprioception, and coordination).

**Diagnosis**

Parasitologic examination of the stool is useful because eggs are abundant in the feces and have morphology distinct from that of all other tapeworms. The eggs are ovoid and have an operculum, which is a cap structure at 1 end that opens to release the embryo (Fig. 302-2). The worm itself has a distinct scolex and proglottid morphology; however, these are not likely to be passed spontaneously.

**Differential Diagnosis**

A segment or a whole section of the worm might be confused with *Taenia* or *Ascaris* after it is passed. Pernicious anemia, bone marrow toxins, and dietary restriction may contribute to or mimic the nutritional deficiencies associated with diphyllobothriasis.

**Treatment**

As with all adult tapeworms, *D. latum* infections respond to praziquantel (5-10 mg/kg PO once). Niclosamide (50 mg/kg in a single oral dose) is also effective.

**Prevention**

The intermediate stage is easily killed by brief cooking or prolonged freezing of fish prior to ingestion. Because humans are the major reservoir for adult worms, health education is one of the most important tools for preventing transmission, together with improved human sanitation.
HYMENOLEPIASIS (HYMENOLEPIS)
Infection with Hymenolepis nana, the dwarf tapeworm, is very common in developing countries. It is a major cause of eosinophilia, and although it rarely causes overt disease, the presence of H. nana eggs in stool may serve as a marker for exposure to poor hygienic conditions and the risk of additional fecal-oral contamination. The intermediate stage of Hymenolepis diminuta develop in various hosts (e.g., rodents, ticks, and fleas), but the entire life cycle of H. nana is completed in humans. Therefore, hyperinfection with thousands of small adult worms in a single child may occur. A similar infection may occur less commonly with the species H. diminuta. Eggs but not segments may be found in the stool. H. nana infection responds to praziquantel (25 mg/kg PO once). Nitazoxanide is effective in about three-fourths of children (100 mg by mouth twice daily for 3 days for children 1-3 yr of age, 200 mg by mouth twice daily for 3 days for children 4-11 yr of age, and 500 mg by mouth twice daily for 3 days for older children).

DIPYLIDIASIS (DIPYLIDIUM CANINUM)
Dipylidium caninum is a common tapeworm of domestic dogs and cat. Human infection is relatively rare. Direct transmission between pets and humans does not occur; human infection requires ingestion of the parasite’s intermediate host, the dog or cat flea. Infants and small children are particularly susceptible because of their level of hygiene, generally more intimate contact with pets, and activities in areas where fleas can be encountered. Thus, children are most at risk of inadvertent ingestion of fleas infected with the larvae. The most common symptoms is passage of proglottids in stool. The proglottids are similar in size and shape to white rice grains. Anal pruritus, vague abdominal pain, and diarrhea have at times been associated with dipylidiasis, which is thus sometimes confused with pinworm (E. vermicularis). Dipylidiasis responds to treatment with praziquantel (5-10 mg/kg PO once) and niclosamide (50 mg/kg orally as a single dose). Deworming of pets and flea control are the best preventive measures.

Cysticercosis

A. Clinton White Jr. and Philip R. Fischer

ETIOLOGY

*Taenia solium*, also known as the pork tapeworm, causes 2 different infections in children. In its normal lifecycle, children can acquire the tapeworm form by ingestion of undercooked pork containing the larvae cysts (see Chapter 302). In the intestines, the cyst converts into the tapeworm form. Children are also susceptible to infection by the eggs shed by tapeworm carriers. After the eggs are ingested, the larvae are released from the eggs, invade through the intestines, and migrate through the bloodstream to the muscles (and other organs), where they form tissue cysts (0.2-2.0 cm fluid-filled bladders containing a single invaginated scolex). Infection with the cystic form is termed cysticercosis, and involvement of the central nervous system is termed neurocysticercosis. The tapeworm form only develops after ingestion of undercooked pork. Ingestion of pork is not necessary to develop cysticercosis, but individuals harboring an adult worm may infect themselves with the eggs by the fecal-oral route.

EPIDEMIOLOGY

The pork tapeworm is widely distributed wherever pigs are raised and have contact with human fecal material. Intense transmission occurs in Central and South America, southern and Southeast Asia, and much of sub-Saharan Africa. In these areas, approximately 30% of cases of seizures may be a result of cysticercosis. Most cases of cysticercosis in the United States are imported; however local transmission has been rarely documented.

PATHOGENESIS

Living, intact cystic stages usually suppress the host immune and inflammatory responses. Intact cysts can be associated with disease when they obstruct the flow of cerebrospinal fluid. Most cysts remain asymptomatic for a few years. Symptoms typically develop as the cysticerci begin to degenerate, associated with a host inflammatory response. The natural history of cysts is to eventually resolve by complete resorption or calcification, but this process may take years. Cysticerci can also present as subcutaneous nodules, ocular infection, or spinal lesions with myelopathy or radiculopathy.

CLINICAL MANIFESTATIONS

Seizures are the presenting finding in the vast majority of children with neurocysticercosis. Less-common manifestations include hydrocephalus, diffuse cerebral edema, or focal neurologic findings. It is important to classify neurocysticercosis as parenchymal, intraventricular, subarachnoid, spinal, or ocular on the basis of anatomic location, clinical presentation, and radiologic appearance since the prognosis and management vary with location.

  Parenchymal neurocysticercosis typically presents with seizures. The seizures are usually focal, but often generalize. Children may present with a single seizure or recurrent epilepsy. Mild neurocognitive defects have been documented from cysticerci alone, but are more commonly associated with poorly controlled seizures. A fulminant encephalitis-like presentation may rarely occur, after a massive initial infection associated with cerebral edema. Intraventricular neurocysticercosis (up to 20% of cases) is associated with obstructive hydrocephalus and acute, subacute, or intermittent signs of increased intracranial pressure, usually without localizing signs. Subarachnoid neurocysticercosis is rare in children. It can be associated with basilar arachnoiditis that can present with signs of meningeal irritation, communicating hydrocephalus, cerebral infarction, or spinal disease with radiculitis or transverse myelitis. Cysticerci in the tissues may present with focal findings from mass effect. Ocular neurocysticercosis causes decreased visual acuity because of cysticerci in the retina or vitreous, retinal detachment, or iridocyclitis.

DIAGNOSIS

Neurocysticercosis should be suspected in a child with onset of seizures or hydrocephalus and who also has a history of residence in an endemic area or a care provider from an endemic area. The most useful diagnostic study for parenchymal disease is MRI of the head. MRI provides the most information about cyst location, viability, and associated inflammation. The protoscolex is sometimes visible within the cyst, which provides a pathognomonic sign for cysticercosis (Fig. 303-1A). The MRI also better detects basilar arachnoiditis (Fig. 303-1B), intraventricular cysts (Fig. 303-1C), and cysts in the spinal cord. CT is best for identifying calcifications. A solitary parenchymal cyst, with or without contrast enhancement, and central nervous system calcifications are the most common findings in children (Fig. 303-2). Plain films may reveal calcifications in muscle or brain consistent with cysticercosis. In children from endemic regions, the presentation with a single enhancing lesion that is round and <2 cm in diameter, absence of symptoms or signs of other diseases (e.g., no fever or lymph nodes), no local findings, and no evidence of increased intracranial pressure is highly specific for neurocysticercosis.

SEROLOGIC DIAGNOSIS

Serologic diagnosis using the enzyme-linked immunotransfer blot is available commercially in the United States and through the Centers for Disease Control and Prevention. Serum antibody testing is highly specific, but is frequently negative in children with single lesions or just calcifications. Antigen-detection assays and polymerase chain reaction assays show promise as diagnostic procedures but are currently not commercially available.
Figure 303-1  A, MRI (T1 weighted) demonstrating 2 parenchymal cysts with protoscoleces.  B, MRI (T1 weighted) of cysticercal basilar arachnoiditis.  C, MRI (T1 weighted) showing a cyst below the fourth ventricle (arrow).  D, MRI (T2 weighted) showing a cysticercus (C) above the optic nerve (ON).

Figure 303-2  CT image of a solitary lesion of neurocysticercosis with (A) and without (B) contrast, showing contrast enhancement.  (Courtesy of Dr. Wendy G. Mitchell and Dr. Marvin D. Nelson, Children’s Hospital, Los Angeles.)
DIFFERENTIAL DIAGNOSIS
Neurocysticercosis is often confused clinically with other seizure disorders. Clinical suspicion is based on travel history, a history of contact with an individual who might carry an adult tapeworm, or suggestive imaging studies. The imaging appearance can be confused with brain abscess, granulomas (including tuberculosis, fungal infections, Langherans histiocytosis, and toxoplasmosis), and tumors.

TREATMENT
The initial management of cysticercosis should focus on symptomatic therapy for seizures and/or hydrocephalus. Seizures can usually be controlled using standard antiepileptic drugs. If the lesions resolve, antiepileptic drugs can often be tapered off. Frequent seizures or the development of calcified lesions are risk factors for recurrent seizures and indications for prolonged or lifelong antiepileptic therapy.

The natural history of parenchymal lesions is to resolve spontaneously with or without antiparasitic drugs, but this process is often prolonged (months to years). Solitary parenchymal cysts resolve slightly more rapidly with antiparasitic therapy. Antiparasitic drugs also decrease the frequency of recurrent seizures. Other forms of the disease are less common in children. In adults with cystic lesions, randomized, controlled trials suggested an overall 2-fold decrease in recurrence of generalized seizures with albendazole treatment. The benefit to children was significantly less, perhaps because most of these infections were with only 1-2 cysts. Corticosteroids likely also decrease seizure frequency.

Albendazole is the most commonly used antiparasitic (15 mg/kg/day PO divided bid). It can be taken with a fatty meal to improve absorption. The most common duration of therapy is 7 days for parenchymal lesions. However, longer duration (months), higher doses (up to 30 mg/kg/day), or combination therapy with praziquantel is often required for multiple lesions or subarachnoid disease. Praziquantel (50-100 mg/kg/day PO divided tid for 28 days) can be used with albendazole or as an alternative to it. First-pass metabolism is common with corticosteroids or antiepileptic drugs. Cimetidine can be used in conjunction with praziquantel to blunt the first-pass metabolism. A worsening of symptoms can follow the use of either drug based on the host's inflammatory response to the dying parasite. Patients should be medicated with prednisone 1-2 mg/kg per day or oral dexamethasone 0.15 mg/kg per day beginning before the first dose of antiparasitic drugs and continuing for at least 2 wk. Methotrexate can be used as a steroid-sparing agent in patients requiring prolonged antiinflammatory therapy.

Most patients with hydrocephalus require neurosurgical interventions. Some cases require emergent placement of a ventriculostomy, but most can be managed by cysticerci in the lateral or third ventricle. Cysticerci in the fourth ventricle can be removed by either flexible endoscopy or via a suboccipital craniotomy. Adherent cysticerci that cannot be removed can be treated by placement of a ventriculoperitoneal shunt. However, there is a high rate of shunt failure, which can be minimized somewhat by treatment with antiparasitic drugs plus corticosteroids.

Subarachnoid disease has a poor prognosis. However, recent studies suggest that the prognosis is much improved by aggressive therapy, including antiparasitic drugs, antiinflammatory treatment, and neurosurgical procedures for hydrocephalus (e.g., placement of a ventriculoperitoneal shunt). However, the dose and duration of antiparasitic and antiinflammatory therapy often need to be prolonged. Ocular cysticercosis is usually treated surgically, although there are reports of cure using medical therapy alone.

PREVENTION
In areas with evolved public health systems, cysticercosis can largely be eliminated by meat inspection, condemnation of infected meat, and thorough cooking of pork. This approach has not worked in countries where most meat is butchered informally. Mass chemotherapy for tapeworm carriers, mass treatment of pigs, and improved personal hygiene have decreased or eliminated transmission in some areas. Screening family members and those preparing food for index cases for cysticercosis has a very low yield, in part because of the poor sensitivity of current tests. Those who have noted passing material consistent with taeniasis should be treated with praziquantel regardless of the results of stool studies. Veterinary vaccines for several cestode infections have a high degree of efficacy and have a potential role in decreasing parasite transmission.

Bibliography is available at Expert Consult.
Bibliography
ETIOLOGY

Echinococcosis (hydatid disease or hydatidosis) is a widespread, serious human cestode infection (Fig. 304-1). Two major Echinococcus groups of species are responsible for distinct clinical presentations. *Echinococcus granulosus* and related species cause cystic hydatid disease. The organisms were, until recently, thought to be a single species, but recent molecular data have confirmed that there are a number of different species and genotypes in what was formally thought to be a single species. *Echinococcus multilocularis* causes alveolar hydatid disease. The adult parasites are a small (2-7 mm) tape-worm with only 2-6 segments that inhabit the intestines of dogs, wolves, dingoes, jackals, coyotes, and foxes. These carnivores pass the eggs in their stool, which contaminates the soil, pasture, and water, as well as their own fur. Domestic animals, such as sheep, goats, cattle, and camels, ingest *E. granulosus* complex eggs while grazing. Humans are also infected by consuming eggs by direct contact with infected dogs or from ova in the environment. The larvae hatch, penetrate the gut, and are carried by the vascular or lymphatic systems to the liver, lungs, and less commonly bones, brain, or heart.

The different species within the *E. granulosus* complex show significant variation in both ecology and genetics. One distinct variant is found in a sylvatic wolf/moose cycle in North America and Siberia. For *E. multilocularis*, the main intermediate hosts are small rodents. The rodents are consumed by foxes, wolves, and other natural predators. In Europe, contamination of gardens by fox excrement is a major risk factor for transmission. Ingestion of infected rodents by dogs can also facilitate transmissions to children.

EPIDEMIOLOGY

There is potential for transmission of this parasite to humans wherever dogs are allowed to ingest the entrails of herd animals. Cysts have been detected in up to 10% of the human population in northern Kenya and western China. Disease is highly endemic in the Middle East and Central Asia. In South America, the disease is prevalent in shepherding areas of the Andes, the beef-herding areas of the Brazilian/Argentine Pampas, and Uruguay. Among developed countries, the disease is recognized in Italy, Greece, Portugal, Spain, and Australia,
Distribution of *Echinococcus granulosus* and cystic echinococcosis (hydatidosis), worldwide, 2009

**PATHOGENESIS**

*E. granulosus* complex parasites are often acquired in childhood, but liver cysts require many years to become large enough to detect or cause symptoms. In children, the lung is a common site, whereas in adults 70% of cysts develop in the liver. Cysts can also develop in bone, the genitourinary system, spleen, subcutaneous tissues, and brain. The host surrounds the primary cyst with a tough, fibrous capsule. Inside this capsule, the parasite produces a thick lamellar layer with the consistency of a soft-boiled egg white. Inside of the lamellar layer is the thin germinal layer of cells responsible for production of thousands of protoscoleces that remain attached to the wall or float free in the cyst fluid (Video 304-1). Smaller internal daughter cysts may develop within the primary cyst capsule. The fluid in a healthy cyst is clear, colorless, and watery. Rupture of the cyst, which can occur with trauma or during surgery, can be associated with an anaphylactic reaction. Protoscoleces released into the tissues can also develop into new cysts. *E. multilocularis* almost always involves the liver. The lesions grow very slowly and rarely present in children. The secondary reproductive units bud externally and are not confined within a single well-defined structure. Thus, the lesions are often confused with a malignancy. Furthermore, the cyst tissues are poorly demarcated from those of the host, making surgical removal difficult. The secondary cysts are also capable of distant metastatic spread. The growing cyst mass eventually replaces a significant portion of the liver and compromises adjacent tissues and structures.

**CLINICAL MANIFESTATIONS**

In the liver, cysts may remain asymptomatic, may regress spontaneously, or may produce nonspecific symptoms. Symptomatic cysts can cause increased abdominal girth, hepatomegaly, a palpable mass, vomiting, or abdominal pain. Serious complications result from compression of adjacent structures or spillage of cyst contents. Mass effects can be noted in the brain and bone. Anaphylaxis can occur with cyst rupture or spontaneous spillage, from trauma or intraoperatively.
Spillage can also be catastrophic long-term, because each protoscolex can form a new cyst. Jaundice from cystic hydatid disease is rare. In the lung, cysts produce chest pain, cough, or hemoptysis. Fluid from partially ruptured cysts is often noted to be salty.

In alveolar hydatid disease, the proliferating mass may compromise hepatic tissue or the biliary system and causes progressive obstructive jaundice and hepatic failure. Symptoms also occur from expansion of extrahepatic foci.

**DIAGNOSIS**

Symptoms and signs are usually nonspecific (e.g., hepatomegaly or a palpable abdominal mass). Ultrasonography is the most valuable tool for both the diagnosis and treatment of cystic hydatid disease of the liver. The presence of internal membranes or echogenic cyst material (protoscoleces, termed hydatid sand) can be observed in real time to aid in the diagnosis. Ultrasonography can also be used for disease staging used to define optimal therapy (Fig. 304-2). Chest radiographs frequently reveal characteristic rounded masses (Fig. 304-3). Alveolar disease resembles a diffuse solid tumor. CT findings are similar to those of ultrasonography and may at times be useful in distinguishing alveolar from cystic hydatid disease in geographic regions where both occur (Fig. 304-4). CT or MRI is also important in planning a surgical intervention. Lung hydatid disease is usually apparent on chest radiograph (Fig. 304-3).

Serologic studies may be useful in confirming a diagnosis of cystic echinococcosis. The sensitivity is high for hepatic or bone disease, but the false-negative rate may be >50% with pulmonary or central nervous system infection.

**DIFFERENTIAL DIAGNOSIS**

Benign hepatic cysts are common but can be distinguished from cystic hydatid disease by the absence of a distinct wall, internal membranes, and hydatid sand. The density of bacterial hepatic abscesses is distinct from the watery cystic fluid characteristic of *E. granulosus* infection, but hydatid cysts may also be complicated by secondary bacterial infection. Alveolar echinococcosis is often confused with hepatoma or metastatic tumor.

**TREATMENT**

Management of cystic hydatid disease should be individualized and guided by disease stage. Approaches range from surgical resection for complicated disease to watchful waiting for cysts that are already degenerating. For small cystic lesions (cystic echinococcosis [CE] types 1 or 3; see Fig. 304-2) that are <5 cm in diameter, albendazole chemotherapy alone (15 mg/kg/day divided bid PO for 1-6 mo; maximum: 800 mg/day) may result in a high rate of cure. Adverse effects include occasional alopecia, mild gastrointestinal disturbance, and elevated transaminases on prolonged use. Because of leukopenia, the FDA recommends that blood counts be monitored at the beginning and every 2 wk during therapy. Chemotherapy may also be used for cysts that are not suitable to PAIR (percutaneous aspiration, instillation, and reaspiration) or operative management.

For larger CE1 and CE3 lesions, ultrasound- or CT-guided PAIR is the preferred therapy. Compared with surgical treatment alone, PAIR plus albendazole therapy is associated with fewer adverse events and fewer days in the hospital. Spillage with PAIR is surprisingly uncommon, but prophylactic albendazole therapy is routinely administered more than 1 wk prior to PAIR therapy and should be continued for at least 1 mo afterward. PAIR is contraindicated in pregnancy and for bile-stained cysts, which should not be injected with a scleroidal agent because of increased risk for biliary complications. In experienced centers, cysts with thick internal septation (CE2) can be managed using a trochar to break up the membranes and external drainage or with surgery.

Surgery is the treatment of choice for complicated cysts, including ruptured cysts, cysts communicating with the biliary tract, large pulmonary cysts, or cysts of the central nervous system or bones.

For conventional surgery, the inner cyst wall (only laminate and germinal layers are of parasite origin) can be easily peeled from the CE1 (type I) Fluid collection (hyaline) CE2 (type II) Multivesicular CE3 (type III) Fluid collection with split wall CE4 (type IV) Heterogeneous pattern CE5 (type V) Calcified

**Figure 304-2 Ultrasound classification of cystic echinococcosis (CE) cysts.** The WHO informal working group on echinococcosis classification differs from that of Gharbi and colleagues by the addition of a “cystic lesion” (CL) stage (undifferentiated) (not shown), and by reversing the order of CE types 2 and 3. CE3 transitional cysts may be differentiated into CE3a (with detached endocyst) and CE3b (predominantly solid with daughter vesicles). CE1 and CE3a are early stage cysts and CE4 and CE5 late stage cysts. (From McManus DP, Gray DJ, Zhang W, Yang Y: Diagnosis, treatment, and management of echinococcosis. BMJ 344:e3866, 2012, Fig. 4.)
Infectious Diseases continued for 6-8 wk postoperatively. CE4 and CE5 cysts are in the process of degeneration and usually do not require specific therapy. They can be managed with serial imaging studies to document resolution (watch and wait). Small thoracic cysts may resolve with chemotherapy, but most cysts require operative removal.

Alveolar hydatidosis frequently requires radical surgery, including partial hepatectomy, lobectomy, or liver transplantation. Medical therapy with albendazole should be continued for 2 yr after presumably curative surgery. In patients who are not operative candidates or whose lesions are not amenable to surgical cure, albendazole long-term suppressive therapy should be used to slow the progression, but the infection generally recurs if albendazole is stopped.

PROGNOSIS
Factors predictive of success with chemotherapy are age of the cyst (<2 yr), low internal complexity of the cyst, and small size. The site of the cyst is not important, although cysts in bone respond poorly. For alveolar hydatidosis, if surgical removal is unsuccessful, the average mortality is 92% by 10 yr after diagnosis.

PREVENTION
Important measures to interrupt transmission include, above all, thorough handwashing, avoiding contact with dogs in endemic areas, boiling or filtering water when camping, proper disposal of animal carcasses, and proper meat inspection. Strict procedures for proper disposal of refuse from slaughterhouses must be instituted and followed so that dogs and wild carnivores do not have access to entrails. Other useful measures are control or treatment of the feral dog population and regular praziquantel treatment of pets and working dogs in endemic areas. Vaccines have been developed to prevent infection in grazing animals but are not widely used.

Chapter 304  Echinococcosis (Echinococcus granulosus and Echinococcus multilocularis)

Bibliography

Gastrointestinal function varies with maturity; what is a physiologic event in a newborn or infant might be a pathologic symptom at an older age. A fetus can swallow amniotic fluid as early as 12 wk of gestation, but nutritive sucking in neonates first develops at about 34 wk of gestation. The coordinated oral and pharyngeal movements necessary for swallowing solids develop within the 1st few mo of life. Before this time, the tongue thrust is upward and outward to express milk from the nipple, instead of a backward motion, which propels solids toward the esophageal inlet. By 1 mo of age, infants appear to show preferences for sweet and salty foods. Infants' interest in solids increases at approximately 4 mo of age. The recommendation to begin solids at 6 mo of age is based on nutritional and cultural concepts rather than maturation of the swallowing process (see Chapter 45). Infants swallow air during feeding, and burping is encouraged to prevent gaseous distention of the stomach.

A number of normal anatomic variations may be noted in the mouth. A short lingual frenulum ("tongue-tie") may be worrisome to parents but only rarely interferes with eating or speech, generally requiring no treatment. Surface furrowing of the tongue (a geographic or scrotal tongue) is usually a normal finding. A bifid uvula may be normal or associated with a submucous cleft of the soft palate.

Regurgitation, the result of gastroesophageal reflux, occurs commonly in the 1st yr of life. Effortless regurgitation can dribble out of an infant's mouth but also may be forceful. In an otherwise healthy infant with regurgitation, volumes of emesis are commonly approximately 15-30 mL but occasionally are larger. Most often, the infant remains happy, although possibly hungry, after an episode of regurgitation. Episodes can occur from one to several times per day. Regurgitation gradually resolves in 80% of infants by 6 mo of age and in 90% by 12 mo. If complications develop or regurgitation persists, gastroesophageal reflux is considered pathologic rather than merely developmental and deserves further evaluation and treatment. Complications of gastroesophageal reflux include failure to thrive, pulmonary disease (apnea or aspiration pneumonitis), and esophagitis with its sequelae (see Chapters 323 and 324).

Infants and young children may be erratic eaters; this may be a worry to parents. A toddler might eat insatiably or refuse to consume food during a meal. Toddlers and young children also tend to eat only a limited variety of foods. Parents should be encouraged to view nutritional intake over several days and not be overly concerned about individual meals. Infancy and adolescence are periods of rapid growth; high nutrient requirements for growth may be associated with voracious appetites. The reduced appetite of toddlers and preschool children is often a worry to parents who are used to the relatively greater dietary intake during infancy. Demonstration of age-appropriate growth on a growth curve is reassuring.

The number, color, and consistency of stools can vary greatly in the same infant and between infants of similar age without apparent explanation. The earliest stools after birth consist of meconium, a dark, viscous material that is normally passed within the 1st 48 hr of life. With the onset of feeding, meconium is replaced by green-brown transition stools, often containing curds, and, after 4-5 days, by yellow-brown milk stools. Stool frequency is extremely variable in normal infants and can vary from none to 7 per day. Breastfed infants can have frequent small, loose stools early (transition stools), and then after 2-3 wk can have very infrequent soft stools. Some nursing infants might not pass any stool for 1-2 wk and then have a normal soft bowel movement. The color of stool has little significance except for the presence of blood or absence of bilirubin products (white-gray rather than yellow-brown). The presence of vegetable matter, such as peas or corn, in the stool of an older infant or toddler ingesting solids is normal and suggests poor chewing and not malabsorption. A pattern of intermittent loose stools, known as toddler's diarrhea, occurs commonly between 1 and 3 yr of age. These otherwise healthy growing children often drink excessive carbohydrate-containing beverages. The stools typically occur during the day and not overnight. The volume of fluid intake is often excessive; limiting sugar and unabsorbable carbohydrate-containing beverages and increasing fat in the diet often leads to resolution of the pattern of loose stools.

A protuberant abdomen is often noted in infants and toddlers, especially after large feedings. This can result from the combination of weak abdominal musculature, relatively large abdominal organs, and lorderotic stance. In the 1st yr of life, it is common to palpate the liver 1-2 cm below the right costal margin. The normal liver is soft in consistency and percutaneous to normal size for age. A Riedel lobe is a thin projection of the right lobe of the liver that may be palpated low in the right lateral abdomen. A soft spleen tip might also be palpable as a normal finding. In thin young children, the vertebral column is easily palpable, and an overlying structure may be mistaken for a mass. Pulsation of the aorta can be appreciated. Normal stool can often be palpated in the left lower quadrant in the descending or sigmoid colon.

Blood loss from the gastrointestinal tract is never normal, but swallowed blood may be misinterpreted as gastrointestinal bleeding. Maternal blood may be ingested at the time of birth or later by a nursing infant if there is bleeding near the mother's nipple. Nasal or oropharyngeal bleeding is occasionally mistaken for gastrointestinal bleeding (see Chapter 103.4). Red dyes in foods or drinks can turn the stool red but do not produce a positive test result for occult blood.

Jaundice is common in neonates, especially among premature infants, and usually results from the inability of an immature liver to conjugate bilirubin, leading to an elevated indirect component (see Chapter 102.4). Persistent elevation of indirect bilirubin levels in nursing infants may be a result of breast milk jaundice, which is usually a benign entity in full-term infants. An elevated direct bilirubin is not normal and suggests liver disease, although in infants it may be a result of extrahepatic infection (urinary tract infection). The direct bilirubin fraction should account for no more than 15-20% of the total serum bilirubin. Elevations in direct bilirubin levels can follow indirect hyperbilirubinemia as the liver converts excess indirect to direct bilirubin and the rate-limiting step in bilirubin excretion shifts from the glucuronidation of bilirubin to excretion of direct bilirubin into the bile canaliculus. Indirect hyperbilirubinemia, which occurs commonly in normal newborns, tends to tint the sclerae and skin golden yellow, whereas direct hyperbilirubinemia produces a greenish yellow hue.
Disorders of organs outside the gastrointestinal (GI) tract can produce symptoms and signs that mimic digestive tract disorders and should be considered in the differential diagnosis (Table 306-1). In children with normal growth and development, treatment may be initiated without a formal evaluation based on a presumptive diagnosis after taking a history and performing a physical examination. Poor weight gain or weight loss is often associated with a significant pathologic process and usually necessitates a more formal evaluation.

**DYSPHAGIA**

Difficulty in swallowing is termed *dysphagia*. Painful swallowing is termed *odynophagia*. *Globus is the sensation of something stuck in the throat without a clear etiology.* Swallowing is a complex process that starts in the mouth with mastication and lubrication of food that is formed into a bolus. The bolus is pushed into the pharynx by the tongue. The pharyngeal phase of swallowing is rapid and involves protective mechanisms to prevent food from entering the airway. The epiglottis is lowered over the larynx while the soft palate is elevated against the nasopharyngeal wall; respiration is temporarily arrested while the upper esophageal sphincter opens to allow the bolus to enter the esophagus. In the esophagus, peristaltic coordinated muscular contractions push the food bolus toward the stomach. The lower esophageal sphincter relaxes shortly after the upper esophageal sphincter, so liquids that rapidly clear the esophagus enter the stomach without resistance.

Dysphagia is classified as oropharyngeal dysphagia and esophageal dysphagia. *Oropharyngeal dysphagia* occurs when the transfer of the food bolus from the mouth to the esophagus is impaired (also termed *transfer dysphagia*). The striated muscles of the mouth, pharynx, and upper esophageal sphincter are affected in oropharyngeal dysphagia. Neurologic and muscular disorders can give rise to oropharyngeal dysphagia (Table 306-2). The most serious complication of oropharyngeal dysphagia is life-threatening aspiration.

A complex sequence of neuromuscular events is involved in the transfer of foods to the upper esophagus. Abnormalities of the muscles involved in the ingestion process and their innervation, strength, or coordination are associated with transfer dysphagia in infants and children. In such cases, an oropharyngeal problem is usually part of a more generalized neurologic or muscular problem (botulism, diphtheria, neuromuscular disease). Painful oral lesions, such as acute viral stomatitis or trauma, occasionally interfere with ingestion. If the nasal air passage is seriously obstructed, the need for respiration causes severe distress when sucking. Although severe structural, dental, and salivary abnormalities would be expected to create difficulties, ingestion proceeds relatively well in most affected children if they are hungry.

*Esophageal dysphagia* occurs when there is difficulty in transporting the food bolus down the esophagus. Esophageal dysphagia can result from neuromuscular disorders or mechanical obstruction (Table 306-3). Primary motility disorders causing impaired peristaltic function and dysphagia are rare in children. Achalasia is an esophageal motility disorder with associated inability of relaxation of the lower esophageal sphincter, and it rarely occurs in children. Motility of the distal esophagus is disordered after surgical repair of tracheoesophageal fistula or achalasia. Abnormal motility can accompany collagen vascular disorders. Mechanical obstruction can be intrinsic or extrinsic. Intrinsic structural defects cause a fixed impediment to the passage of food bolus because of a narrowing within the esophagus, as in a stricture, web, or tumor. Extrinsic obstruction is

Raman Sreedharan and Chris A. Liacouras
caused by compression from vascular rings, mediastinal lesions, or vertebral abnormalities. Structural defects typically cause more problems in swallowing solids than liquids. In infants, esophageal web, tracheobronchial remnant, or vascular ring can cause dysphagia. An esophageal stricture secondary to esophagitis (chronic gastroesophageal reflux, eosinophilic esophagitis, chronic infections) occasionally has dysphagia as the first manifestation. An esophageal foreign body or a stricture secondary to a caustic ingestion also causes dysphagia. A Schatzki ring, a thin ring of mucosal tissue near the lower esophageal sphincter, is another mechanical cause of recurrent dysphagia, and again is rare in children.

When dysphagia is associated with a delay in passage through the esophagus, the patient may be able to point to the level of the chest where the delay occurs, but esophageal symptoms are usually referred to the suprasternal notch. When a patient points to the suprasternal notch, the impaction can be found anywhere in the esophagus.

**REGURGITATION**

Regurgitation is the effortless movement of stomach contents into the esophagus and mouth. It is not associated with distress, and infants with regurgitation are often hungry immediately after an episode. The lower esophageal sphincter prevents reflux of gastric contents into the esophagus. Regurgitation is a result of gastroesophageal reflux through an incompetent or, in infants, immature lower esophageal sphincter. This is often a developmental process, and regurgitation or “spitting” resolves with maturity. Regurgitation should be differentiated from vomiting, which denotes an active reflex process with an extensive differential diagnosis (Table 306-4).

**ANOREXIA**

Anorexia means prolonged lack of appetite. Hunger and satiety centers are located in the hypothalamus; it seems likely that afferent nerves from the GI tract to these brain centers are important determinants of the anorexia that characterizes many diseases of the stomach and intestine (see Chapter 47). Satiety is stimulated by distention of the stomach or upper small bowel, the signal being transmitted by sensory afferents, which are especially dense in the upper gut. Chemoreceptors in the intestine, influenced by the assimilation of nutrients, also affect afferent flow to the appetite centers. Impulses reach the hypothalamus from higher centers, possibly influenced by pain or the emotional disturbance of an intestinal disease. Other regulatory factors include hormones, ghrelin, leptin, and plasma glucose, which, in turn, reflect intestinal function (see Chapter 47).

**VOMITING**

Vomiting is a highly coordinated reflex process that may be preceded by increased salivation and begins with involuntary retching. Violent descent of the diaphragm and constriction of the abdominal muscles with relaxation of the gastric cardia actively force gastric contents back up the esophagus. This process is coordinated in the medullary vomiting center, which is influenced directly by afferent innervation and indirectly by the chemoreceptor trigger zone and higher central nervous system (CNS) centers. Many acute or chronic processes can cause vomiting (see Tables 306-1 and 306-4).

Vomiting caused by obstruction of the GI tract is probably mediated by increased visceral afferent nerves stimulating the vomiting center (Table 306-5). If obstruction occurs below the second part of the duodenum, vomitus is usually bile stained. Emesis can also become bile stained with repeated vomiting in the absence of obstruction when duodenal contents are refluxed into the stomach. Nonobstructive lesions of the digestive tract can also cause vomiting; this includes diseases of the upper bowel, pancreas, liver, or biliary tree. CNS or metabolic derangements can lead to severe, persistent emesis.

**Cyclic vomiting** is a syndrome with numerous episodes of vomiting interspersed with well intervals. The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition consensus statement on the diagnosis and management of cyclic vomiting criteria are listed in Table 306-6. Rome III criteria for functional GI disorders have 2 criteria for cyclic vomiting in children, and both these criteria have to

be present for a diagnosis of cyclic vomiting: 2 or more periods of intense nausea and unremitting vomiting or retching lasting hours to days and return to usual state of health lasting weeks to months.

The onset of cyclic vomiting is usually between 2 and 5 yr of age but has been observed in infants and adults. The frequency of vomiting episodes is variable (average of 12 episodes per yr) with each episode typically lasting 2-3 days and 4 or more emesis episodes per hour. The episodes usually occur in the early hours of the morning or upon waking. Patients can have a prorome of nausea, pallor, intolerance of noise or light, lethargy, and headache. Epigastric pain, abdominal pain, diarreha, and fever are seen in many patients, making the diagnosis difficult. Precipitants include infection, physical stress, and psychologic stress.

Several theories have been proposed as causative factors, including a migraine-related mechanism, mitochondrial disorders, and autonomic dysfunction. More than 80% of affected children have a 1st-degree relative with migraines; many patients develop migraines later in life. Many children show evidence for sympathethic autonomic dysfunction of sudomotor systems. The differential diagnosis includes GI anomalies (malrotation, duplication cysts, choledochal cysts, reeruptent intussusceptions), CNS disorders (neoplasm, epilepsy, vestibular pathology), nephrolithiasis, choledolithiasis, hydrenephrosis, metabolic-dysfunction of sudomotor systems. The differential diagnosis includes GI anomalies (malrotation, duplication cysts, choledochal cysts, recurrent intussusceptions), CNS disorders (neoplasm, epilepsy, vestibular pathology), nephrolithiasis, choledolithiasis, hydrenephrosis, metabolic-
Osmotic diarrhea occurs after ingestion of a poorly absorbed solute. The solute may be one that is normally not well absorbed (magnesium, phosphate, lactulose, or sorbitol) or one that is not well absorbed because of a disorder of the small bowel (lactose with lactase deficiency or glucose with rotavirus diarrhea). Malabsorbed carbohydrate is fermented in the colon, and short-chain fatty acids are produced. Although short-chain fatty acids can be absorbed in the colon and used as an energy source, the net effect is increase in the osmotic solute load. This form of diarrhea is usually of lesser volume than a secretory diarrhea and stops with fasting. The osmolality of the stool will not be explained by the electrolyte content, because another osmotic component is present and so the anion gap is >100 mOsm.

COMPLICATIONS

- Dehydration: IV fluids, electrolytes
- Hematemesis: Transfuse, correct coagulopathy
- Esophagitis: H2RAs, PPIs
- Malnutrition: NG or NJ drip feeding useful for many chronic conditions
- Meconium ileus: Gastrografin enema
- DIOS: Gastrografin enema; balanced colonic lavage solution (e.g., GoLYTELY)
- Intussusception: Barium enema; air reduction enema
- Hematemesis: Endoscopic: injection sclerotherapy or banding of esophageal varices; injection therapy, fibrin sealant application, or heater probe electrocautery for selected upper GI tract lesions
- Sigmoid volvulus: Colonoscopic decompression
- Reflux: Positioning; dietary measures (infants: rice cereal, 1 tbs/oz of formula)
- Psychogenic components: Psychotherapy; tricyclic antidepressants; anxiolytics (e.g., diazepam: 0.1 mg/kg PO tid-qid)

DIOS, distal intestinal obstruction syndrome; GI, gastrointestinal; H2RA, H2-receptor antagonist; NG, nasogastric; NJ, nasojejunal; PPIs, proton pump inhibitors; tbs, tablespoon.

VIP, vasoactive intestinal peptide; WBC, white blood cell.

Motility disorders can be associated with rapid or delayed transit and are not generally associated with large-volume diarrhea. Slow motility can be associated with bacterial overgrowth leading to diarrhea. The differential diagnosis of common causes of acute and chronic diarrhea is noted in Table 306-11.

CONSTIPATION

Any definition of constipation is relative and depends on stool consistency, stool frequency, and difficulty in passing the stool. A normal child might have a soft stool only every 2nd or 3rd day without difficulty; this is not constipation. A hard stool passed with difficulty every 3rd day should be treated as constipation. Constipation can arise from defects either in filling or emptying the rectum (Table 306-12).

A nursing infant might have very infrequent stools of normal consistency; this is usually a normal pattern. True constipation in the neonatal period is most likely secondary to Hirschsprung disease, intestinal pseudoobstruction, or hypothyroidism.

Defective rectal filling occurs when colonic peristalsis is ineffective (in cases of hypothyroidism or opiate use and when bowel obstruction is caused either by a structural anomaly or by Hirschsprung disease).
The resultant colonic stasis leads to excessive drying of stool and a failure to initiate reflexes from the rectum that normally trigger evacuation. Emptying the rectum by spontaneous evacuation depends on a defecation reflex initiated by pressure receptors in the rectal muscle. Stool retention, therefore, can also result from lesions involving these rectal muscles, the sacral spinal cord afferent and efferent fibers, or the muscles of the abdomen and pelvic floor. Disorders of anal sphincter relaxation can also contribute to fecal retention.

Constipation tends to be self-perpetuating, whatever its cause. Hard, large stools in the rectum become difficult and even painful to evacuate; thus, more retention occurs and a vicious circle ensues. Distention of the rectum and colon lessens the sensitivity of the defecation reflex and the effectiveness of peristalsis. Fecal impaction is common and leads to other problems. Eventually, watery content from the proximal colon might percolate around hard retained stool and pass per rectum unperceived by the child. This involuntary encopresis may be mistaken for diarrhea. Constipation itself does not have deleterious systemic effects, but urinary tract stasis can accompany severe long-standing cases and constipation can generate anxiety, having a marked emotional impact on the patient and family.

**ABDOMINAL PAIN**

There is considerable variation among children in their perception and tolerance for abdominal pain. This is one reason the evaluation of chronic abdominal pain is difficult. A child with functional abdominal pain (no identifiable organic cause) may be as uncomfortable as one with an organic cause. It is very important to distinguish between organic and nonorganic (functional) abdominal pain because the approach for the management is based on this. Normal growth and physical examination (including a rectal examination) and the absence of anemia or hematochezia are reassuring in a child who is suspected of having functional pain.

A specific cause may be difficult to find, but the nature and location of a pain-provoking lesion can usually be determined from the clinical description. Two types of nerve fibers transmit painful stimuli in the abdomen. In skin and muscle, A fibers mediate sharp localized pain; C fibers from viscera, peritoneum, and muscle transmit poorly localized, dull pain. These afferent fibers have cell bodies in the dorsal root ganglia, and some axons cross the midline and ascend to the medulla, midbrain, and thalamus. Pain is perceived in the cortex of the postcentral gyrus, which can receive impulses arising from both sides of the body. In the gut, the usual stimulus provoking pain is tension or stretching. Inflammatory lesions can lower the pain threshold, but the mechanisms producing pain of inflammation are not clear. Tissue metabolites released near nerve endings probably account for the pain caused by ischemia. Perception of these painful stimuli can be modulated by input from both cerebral and peripheral sources. Psychologic factors are particularly important. Tables 306-13 and 306-14 list features of abdominal pain. Pain that suggests a potentially serious organic etiology is associated with age younger than 5 yr; fever; weight loss;

bile or blood-stained emesis; jaundice; hepatosplenomegaly; back or flank pain or pain in a location other than the umbilicus; awakening from sleep in pain; referred pain to shoulder, groin or back; elevated erythrocyte sedimentation rate, white blood cell count, or C-reactive protein; anemia; edema; hematochezia, or a strong family history of inflammatory bowel disease or celiac disease.

Visceral pain tends to be dull and aching and is experienced in the dermatome from which the affected organ receives innervations. So, most often, the pain and tenderness is not felt over the site of the disease process. Painful stimuli originating in the liver, pancreas, biliary tree, stomach, or upper bowel are felt in the epigastrium; pain from the distal small bowel, cecum, appendix, or proximal colon is felt at the umbilicus; and pain from the distal large bowel, urinary tract, or pelvic organs is usually suprapubic. The pain from the cecum, ascending colon, and descending colon sometimes is felt at the site of the lesion because of the short mesoecum and corresponding mesocolon. The pain caused by appendicitis is initially felt in the periumbilical region, and pain from the transverse colon is usually felt in the supra pubic region. The shifting (localization) of pain is a pointer toward diagnosis; for example, periumbilical pain of a few hours localizing to the right lower quadrant suggests appendicitis. Radiation of pain can be helpful in diagnosis; for example, in biliary colic the radiation of pain is toward the inferior angle of the right scapula, pancreatic pain radiated to the back, and the renal colic pain is radiated to the inguinal region on the same side.

Somatic pain is intense and is usually well localized. When the inflamed viscus comes in contact with the somatic organ like the parietal peritoneum or the abdominal wall, pain is localized to that site. Peritonitis gives rise to generalized abdominal pain with rigidity, involuntary guarding, rebound tenderness, and cutaneous hyperesthesia on physical examination.

Referred pain from extraintestinal locations, from shared central projections with the sensory pathway from the abdominal wall, can give rise to abdominal pain, as in pneumonia when the parietal pleural pain is referred to the abdomen.

GASTROINTESTINAL HEMORRHAGE

Bleeding can occur anywhere along the GI tract, and identification of the site may be challenging (Table 306-15). Bleeding that originates in the esophagus, stomach, or duodenum can cause hematemesis. When exposed to gastric or intestinal juices, blood quickly darkens to resemble coffee grounds; massive bleeding is likely to be red. Red or maroon blood in stools, hematochezia, signifies either a distal bleeding site or massive hemorrhage above the distal ileum. Moderate to mild bleeding from sites above the distal ileum tends to cause blackened stools of tarry consistency (melena); major hemorrhages in the duodenum or above can also cause melena.

Erosive damage to the mucosa of the GI tract is the most common cause of bleeding, although variceal bleeding secondary to portal hypertension occurs often enough to require consideration. Prolapse gastropathy producing subepithelial hemorrhage and Mallory-Weiss lesions secondary to mucosal tears associated with esmesis are causes of upper intestinal bleeds. Vascular malformations are a rare cause in children; they are difficult to identify. Upper intestinal bleeding is evaluated with esophagogastroduodenoscopy. Evaluation of the small intestine is facilitated by capsule endoscopy. The capsule-sized imaging device is swallowed in older children or placed endoscopically in younger children. Lower GI bleeding is investigated with a colonoscopy. In brisk intestinal bleeding of unknown location, a tagged red blood cell scan is helpful in locating the site of the bleeding. Occult blood in stool is usually detected by using commercially available fecal occult blood testing cards, which are based on a chemical reaction between the chemical guaiac and oxidizing action of a substrate (hemoglobin), giving a blue color. The guaiac test is very sensitive, but random testing can miss chronic blood loss, which can lead to iron-deficiency anemia. GI hemorrhage can produce hypotension and tachycardia but rarely causes GI symptoms; brisk duodenal or gastric bleeding can lead to nausea, vomiting, or diarrhea. The breakdown products of intraluminal blood might tip patients into hepatic coma if liver function is already compromised and can lead to elevation of serum bilirubin.

ABDOMINAL DISTENTION AND ABDOMINAL MASSES

Enlargement of the abdomen can result from diminished tone of the wall musculature or from increased content: fluid, gas, or solid. Ascites, the accumulation of fluid in the peritoneal cavity, distends the abdomen both in the flanks and anteriorly when it is large in volume. This fluid shifts with movement of the patient and conducts a percussion wave. Ascitic fluid is usually a transudate with a low protein concentration resulting from reduced plasma colloid osmotic pressure of hypoalbuminemia and/or from raised portal venous pressure. In cases of portal hypertension, the fluid leak probably occurs from lymphatics on the liver surface and from visceral peritoneal capillaries, but ascites does not usually develop until the serum albumin level falls. Sodium excretion in the urine decreases greatly as the ascitic fluid accumulates and, thus, additional dietary sodium goes directly to the peritoneal space, taking with it more water. When ascitic fluid contains a high protein

**An abdominal organ can enlarge diffusely or be affected by a discrete mass. In the digestive tract, such discrete masses can occur in the lumen, wall, omentum, or mesentery. In a constipated child, mobile, nontender fecal masses are often found. Congenital anomalies, cysts, or inflammatory processes can affect the wall of the gut. Gut wall neoplasms are extremely rare in children. The pathologic enlargement of liver, spleen, bladder, and kidneys can give rise to abdominal distention.**

**JAUNDICE**

See Chapters 102.3 and 356.

*Bibliography is available at Expert Consult.*

...concentration, it is usually an exudate caused by an inflammatory or neoplastic lesion.

When fluid distends the gut, either obstruction or imbalance between absorption and secretion should be suspected. The factors causing fluid accumulation in the bowel lumen often cause gas to accumulate, too. The result may be audible gurgling noises. The source of gas is usually swallowed air, but endogenous flora can increase considerably in malabsorptive states and produce excessive gas when substrate reaches the lower intestine. Gas in the peritoneal cavity (pneumoperitoneum) is usually caused by a perforated viscus and can cause abdominal distention depending on the amount of gas leak. A tympanitic percussion note, even over solid organs such as the liver, indicates a large collection of gas in the peritoneum.

Chapter 307
Development and Developmental Anomalies of the Teeth
Norman Tinanoff

INITIATION
The primary teeth form in dental crypts that arise from a band of epithelial cells incorporated into each developing jaw. By 12 wk of fetal life, each of these epithelial bands (dental laminae) has 5 areas of rapid growth on each side of the maxilla and the mandible, seen as rounded, bud-like enlargements. Organization of adjacent mesenchyme takes place in each area of epithelial growth, and the 2 elements together are the beginning of a tooth.

After the formation of these crypts for the 20 primary teeth, another generation of tooth buds forms lingually (toward the tongue); these will develop into the succeeding permanent incisors, canines, and premolars that eventually replace the primary teeth. This process takes place from approximately 5 mo of gestation for the central incisors to approximately 10 mo of age for the 2nd premolars. The permanent 1st, 2nd, and 3rd molars, on the other hand, arise from extension of the dental laminae distal to the 2nd primary molars; buds for these teeth develop at approximately 4 mo of gestation, 1 yr of age, and 4-5 yr of age, respectively.

HISTODIFFERENTIATION–MORPHODIFFERENTIATION
As the epithelial bud proliferates, the deeper surface invaginates and a mass of mesenchyme becomes partially enclosed. The epithelial cells differentiate into the ameloblasts that lay down an organic matrix that forms enamel; the mesenchyme forms the dentin and dental pulp.

CALCIFICATION
After the organic matrix has been laid down, the deposition of the inorganic mineral crystals takes place from several sites of calcification that later coalesce. The characteristics of the inorganic portions of a tooth can be altered by disturbances in formation of the matrix, decreased availability of minerals, or the incorporation of foreign materials. Such disturbances can affect the color, texture, or thickness of the tooth surface. Calcification of primary teeth begins at 3-4 mo in utero and concludes postnatally at approximately 12 mo with mineralization of the 2nd primary molars (Table 307-1).

ERUPTION
At the time of tooth bud formation, each tooth begins a continuous movement toward the oral cavity. Table 307-1 lists the times of eruption of the primary and permanent teeth.

ANOMALIES ASSOCIATED WITH TOOTH DEVELOPMENT
Both failures and excesses of tooth initiation are observed. Developmentally missing teeth can result from environmental insult, a genetic defect involving only teeth, or the manifestation of a syndrome. Anodontia, or absence of teeth, occurs when no tooth buds form (ectodermal dysplasia, or familial missing teeth) or when there is a disturbance of a normal site of initiation (the area of a palatal cleft). The teeth that are most commonly absent are the 3rd molars, the maxillary lateral incisors, and the mandibular 2nd premolars. If the dental lamina produces more than the normal number of buds, supernumerary teeth occur, most often in the area between the maxillary central incisors. Because they tend to disrupt the position and eruption of the adjacent normal teeth, their identification by radiographic examination is important. Supernumerary teeth also occur with cleidocranial dysplasia (see Chapter 311) and in the area of cleft palates.

Twining, in which 2 teeth are joined together, is most often observed in the mandibular incisors of the primary dentition. It can result from gemination, fusion, or concrescence. Gemination is the result of the division of 1 tooth germ to form a bifid crown on a single root with a common pulp canal; an extra tooth appears to be present in the dental arch. Fusion is the joining of incompletely developed teeth that, owing to pressure, trauma, or crowding, continue to develop as 1 tooth. Fused teeth are sometimes joined along their entire length; in other cases, a single wide crown is supported on 2 roots. Concrescence is the attachment of the roots of closely approximated adjacent teeth by an excessive deposit of cementum. This type of twinning, unlike the others, is found most often in the maxillary molar region.

Disturbances during differentiation can result in alterations in dental morphology, such as macrodontia (large teeth) or microdontia (small teeth). The maxillary lateral incisors can assume a slender, tapering shape (peg-shaped laterals).

Amelogenesis imperfecta represents a group of hereditary conditions that manifest in enamel defects of the primary and permanent teeth without evidence of systemic disorders (Fig. 307-1). The teeth are covered by only a thin layer of abnormally formed enamel through which the yellow underlying dentin is seen. The primary teeth are generally affected more than the permanent teeth. Susceptibility to caries is low, but the enamel is subject to destruction from abrasion. Complete coverage of the crown may be indicated for dentin protection, to reduce tooth sensitivity, and for improved appearance.

Dentinogenesis imperfecta, or hereditary opalescent dentin, is a condition analogous to amelogenesis imperfecta in which the odontoblasts fail to differentiate normally, resulting in poorly calcified dentin (Fig. 307-2). This autosomal dominant disorder can also occur in patients with osteogenesis imperfecta. The enamel-dentin junction is altered, causing enamel to break away. The exposed dentin is then susceptible to abrasion, in some cases worn to the gingiva. The teeth are opaque and pearly, and the pulp chambers are generally obliterated by calcification. Both primary and permanent teeth are usually involved. If there is excessive wear of the teeth, selected complete coverage of the teeth may be indicated to prevent further tooth loss and improve appearance.

Localized disturbances of calcification that correlate with periods of illness, malnutrition, premature birth, or birth trauma are common. Hypocalcification appears as opaque white patches or horizontal lines on the teeth; hypoplasia is more severe and manifests as pitting or areas devoid of enamel. Systemic conditions, such as renal failure and cystic fibrosis, are associated with enamel defects. Local trauma to the primary incisors can also affect calcification of permanent incisors.

Fluorosis (mottled enamel) can result from systemic fluoride consumption > 0.05 mg/kg/day during enamel formation. This high fluoride consumption can be caused by residing in an area of high fluoride content of the drinking water (>2.0 ppm), swallowing excessive fluoridated toothpaste, or inappropriate fluoride prescriptions. Excessive fluoride during enamel formation affects ameloblastic function, resulting in inconspicuous white, lacy patches on the enamel to severe brownish discoloration and hypoplasia. The latter changes are usually seen with fluoride concentrations in the drinking water > 5.0 ppm.

Discolored teeth can result from incorporation of foreign substances into developing enamel. Neonatal hyperbilirubinemia can produce blue to black discoloration of the primary teeth. Porphyria produces a red-brown discoloration. Tetracyclines are extensively incorporated into bones and teeth and, if administered during the period of formation of enamel, can result in brown-yellow discoloration and hypoplasia of the enamel. Such teeth fluoresce under ultraviolet light. The period at risk extends from approximately 4 mo of gestation to 7 yr of life. Repeated or prolonged therapy with tetracycline carries the highest risk.

Delayed eruption of the 20 primary teeth can be familial or indicate systemic or nutritional disturbances such as hypopituitarism, hypothyroidism, cleidocranial dysplasia, trisomy 21, and multiple syndromes. Failure of eruption of single or small groups of teeth can arise from local causes such as malpositioned teeth, supernumerary teeth, cysts, or retained primary teeth. Premature loss of primary teeth is most commonly caused by premature eruption of the permanent teeth. If the entire dentition is advanced for age and sex, precocious puberty or hyperthyroidism should be considered.

Natal teeth are observed in approximately 1 in 2,000 newborn infants usually in the position of the mandibular central incisors. Natal teeth are present at birth, whereas neonatal teeth erupt in the 1st mo of life. Attachment of natal and neonatal teeth is generally limited to the gingival margin, with little root formation or bony support. They may be a supernumerary or a prematurely erupted primary tooth. A radiograph can easily differentiate between the two conditions. Natal teeth are associated with cleft palate, Pierre Robin syndrome, Ellis-van Creveld syndrome, Hallermann-Streiff syndrome, pachyonychia congenita, and other anomalies. A family history of natal teeth or premature eruption is present in 15-20% of affected children.

Natal or neonatal teeth occasionally result in pain and refusal to feed and can produce maternal discomfort because of abrasion or biting of the nipple during nursing. If the tooth is mobile there is a danger of aspiration. Because the tongue lies between the alveolar processes during birth, it can become lacerated (Riga-Fede disease). Decisions regarding extraction of prematurely erupted primary teeth must be made on an individual basis.

Exfoliation failure occurs when a primary tooth is not shed before the eruption of its permanent successor. Most often the primary tooth exfoliates eventually, but in some cases, the primary tooth needs to be extracted. This occurs most commonly in the mandibular incisor region.

Bibliography is available at Expert Consult.
Bibliography
Disorders of the teeth and surrounding structures can occur in isolation or in combination with other systemic conditions (Table 308-1). Most commonly, medical conditions that occur during tooth development can affect tooth formation or appearance. Damage to teeth during their development is permanent.

The oral cavity is essentially a masticatory instrument. The purpose of the anterior teeth is to bite off portions of large amounts of food. The posterior teeth reduce foodstuff to a soft, moist bolus. The cheeks and tongue force the food onto the areas of tooth contact. Establishing a proper relationship between the mandibular and maxillary teeth is important for physiologic and cosmetic reasons.

**VARIATIONS IN GROWTH PATTERNS**

Growth patterns are classified into 3 main types of occlusion, determined when the jaws are closed and the teeth are held together (Fig. 309-1). According to the Angle Classification of Malocclusion, in **class I occlusion** (normal), the cusps of the posterior mandibular teeth interdigitate ahead of and inside of the corresponding cusps of the opposing maxillary teeth. This relationship provides a normal facial profile.

In **class II malocclusion**, “buck teeth,” the cusps of the posterior mandibular teeth are behind and inside the corresponding cusps of the maxillary teeth. This common occlusal disharmony is found in ~45% of the population. The facial profile can give the appearance of a “receding chin” (retrognathia) (mandibular deficiency) or protruding front teeth. The resultant increased space between upper and lower anterior teeth encourage finger sucking and tongue-thrust habits. Additionally, children with pronounced class II malocclusions are at greater risks of damage to the incisors as a consequence of trauma. Treatment includes orthodontic retraction of the maxilla or stimulation of the mandible.

In **class III malocclusion**, “underbite,” the cusps of the posterior mandibular teeth interdigitate a tooth or more ahead of their opposing maxillary counterparts. The anterior teeth appear in crossbite with the mandibular incisors protruding beyond the maxillary incisors. The facial profile gives the appearance of a “protruding chin” (prognathia) with or without an appearance of maxillary deficiency. If necessary, treatment includes mandibular excess reduction osteotomy or orthodontic maxillary facial protrusion.

**CROSSBITE**

Normally, the mandibular teeth are in a position just inside the maxillary teeth, so that the outside mandibular cusps or incisal edges meet the central portion of the opposing maxillary teeth. A reversal of this relation is referred to as a crossbite. Crossbites can be anterior, involving the incisors; can be posterior, involving the molars; or can involve single or multiple teeth.

---

**Figure 309-1** Angle classification of occlusion. The typical correspondence between the facial-jaw profile and molar relationship is shown.
OPEN AND CLOSED BITES
If the posterior mandibular and maxillary teeth make contact with each other, but the anterior teeth are still apart, the condition is called an open bite. Open bites can result from skeletal growth pattern or digit sucking. If digit sucking is terminated before skeletal and dental growth is complete, the open bite might resolve naturally. If mandibular anterior teeth occlude inside the maxillary anterior teeth in an overclosed position, the condition is referred to as a closed or deep bite.

Treatment of open and closed bites consists of orthodontic correction, generally performed in the preteen or teenage years. Some cases require orthognathic surgery to position the jaws optimally in a vertical direction.

DENTAL CROWDING
Overlap of incisors can result when the jaws are too small or the teeth are too large for adequate alignment of the teeth. Growth of the jaws is mostly in the posterior aspects of the mandible and maxilla, and therefore inadequate space for the teeth at 7 or 8 yr of age will not resolve with growth of the jaws. Spacing in the primary dentition is normal and favorable for adequate alignment of successor teeth.

DIGIT SUCKING
Various and conflicting etiologic theories and recommendations for correction have been proposed for digit sucking in children. Prolonged digit sucking can cause flaring of the maxillary incisor teeth, an open bite, and a posterior crossbite. The prevalence of digit sucking decreases steadily from the age of 2 yr to ≈10% by the age of 5 yr. The earlier the habit is discontinued after the eruption of the permanent maxillary incisors (age 7–8 yr), the greater the likelihood that there will be lessening effects on the dentition.

A variety of treatments have been suggested, from behavioral modification to insertion of an appliance with extensions that serves as a reminder when the child attempts to insert the digit. The greatest likelihood of success occurs in cases in which the child desires to stop. Stopping of the habit will not rectify a malocclusion caused by a prior deviant growth pattern.
Clefts of the lip and palate are distinct entities closely related embryologically, functionally, and genetically. It is thought that cleft of the lip appears because of hypoplasia of the mesenchymal layer, resulting in a failure of the medial nasal and maxillary processes to join. Cleft of the palate appears to represent failure of the palatal shelves to approximate or fuse.

INCIDENCE AND EPIDEMIOLOGY
The incidence of cleft lip with or without cleft palate is approximately 1 in 750 white births; the incidence of cleft palate alone is approximately 1 in 2,500 white births. Clefts of the lip are more common in males. Possible causes include maternal drug exposure, a syndrome-malformation complex, or genetic factors. Although clefts of lips and palates appear to occur sporadically, the presence of susceptible genes appears important. There are approximately 400 syndromes associated with cleft lip and palates. There are families in which a cleft lip or palate, or both, is inherited in a dominant fashion (van der Woude syndrome), and careful examination of parents is important to distinguish this type from others, because the recurrence risk is 50%. Ethnic factors also affect the incidence of cleft lip and palate; the incidence is highest among Asians (~1 in 500) and Native Americans (~1 in 300), and lowest among blacks (~1 in 2,500). Cleft lip may be associated with other cranial facial anomalies, whereas cleft palate may be associated with central nervous system anomalies.

CLINICAL MANIFESTATIONS
Cleft lip can vary from a small notch in the vermillion border to a complete separation involving skin, muscle, mucosa, tooth, and bone. Clefts of the lip may be unilateral (more often on the left side) or bilateral and can involve the alveolar ridge (Fig. 310-1).

Isolated cleft palate occurs in the midline and might involve only the uvula or can extend into or through the soft and hard palates to the incisive foramen. When associated with cleft lip, the defect can involve the midline of the soft palate and extend into the hard palate on one or both sides, exposing one or both of the nasal cavities as a unilateral or bilateral cleft palate. The palate can also have a submucosal cleft indicated by a bifid uvula, partial separation of muscle with intact mucosa, or a palpable notch at the posterior of the palate.

TREATMENT
A complete program of habilitation for the child with a cleft lip or palate can require years of special treatment by a team consisting of a pediatrician, plastic surgeon, otolaryngologist, oral and maxillofacial surgeon, pediatric dentist, prosthodontist, orthodontist, speech therapist, geneticist, medical social worker, psychologist, and public health nurse.

The immediate problem in an infant born with a cleft lip or palate is feeding. Although some advocate the construction of a plastic obturator to assist in feedings, most believe that with the use of soft artificial nipples with large openings, a squeezable bottle, and proper instruction, feeding of infants with clefts can be achieved.

Surgical closure of a cleft lip is usually performed by 3 mo of age, when the infant has shown satisfactory weight gain and is free of any oral, respiratory, or systemic infection. Modification of the Millard rotation–advancement technique is the most commonly used technique; a staggered suture line minimizes notching of the lip from retraction of scar tissue. The initial repair may be revised at 4 or 5 yr of age. Corrective surgery on the nose may be delayed until adolescence. Nasal surgery can also be performed at the time of the lip repair. Cosmetic results depend on the extent of the original deformity, healing potential of the individual patient, absence of infection, and the skill of the surgeon.

Because clefts of the palate vary considerably in size, shape, and degree of deformity, the timing of surgical correction should be individualized. Criteria such as width of the cleft, adequacy of the existing palatal segments, morphology of the surrounding areas (width of the oropharynx), and neuromuscular function of the soft palate and pharyngeal walls affect the decision. The goals of surgery are the union of the cleft segments, intelligible and pleasant speech, reduction of nasal regurgitation, and avoidance of injury to the growing maxilla.

In an otherwise healthy child, closure of the palate is usually done before 1 yr of age to enhance normal speech development. When surgical correction is delayed beyond the 3rd yr, a contoured speech bulb can be attached to the posterior of a maxillary denture so that contraction of the pharyngeal and velopharyngeal muscles can bring tissues into contact with the bulb to accomplish occlusion of the nasopharynx and help the child develop intelligible speech.

A cleft palate usually crosses the alveolar ridge and interferes with the formation of teeth in the maxillary anterior region. Teeth in the cleft area may be displaced, malformed, or missing. Missing teeth or teeth that are nonfunctional are replaced by prosthetic devices.

POSTOPERATIVE MANAGEMENT
During the immediate postoperative period, special nursing care is essential. Gentle aspiration of the nasopharynx minimizes the chances of the common complications of atelectasis or pneumonia. The primary considerations in postoperative care are maintenance of a clean suture line and avoidance of tension on the sutures. The infant is fed with a
Velopharyngeal dysfunction may also be demonstrated radiographically. The head should be carefully positioned to obtain a true lateral view; one film is obtained with the patient at rest and another during continuous phonation of the vowel u as in “boom.” The soft palate contacts the posterior pharyngeal wall in normal function, whereas in velopharyngeal dysfunction such contact is absent.

In selected cases of velopharyngeal dysfunction, the palate may be retropositioned or pharyngoplasty may be performed using a flap of tissue from the posterior pharyngeal wall. Dental speech appliances have also been used successfully. The type of surgery used is best tailored to the findings on nasoendoscopy.

Bibliography is available at Expert Consult.

Mead Johnson bottle and the arms are restrained with elbow cuffs. A fluid or semifluid diet is maintained for 3 wk. The patient’s hands, toys, and other foreign bodies must be kept away from the surgical site.

SEQUELAE

Recurrent otitis media and subsequent hearing loss are frequent with cleft palate. Displacement of the maxillary arches and malposition of the teeth usually require orthodontic correction. Misarticulations and velopharyngeal dysfunction are often associated with cleft lip and palate and may be present or persist because of physiologic dysfunction, anatomic insufficiency, malocclusion, or inadequate surgical closure of the palate. Such speech is characterized by the emission of air from the nose and by a hypernasal quality with certain sounds or by compensatory misarticulations (glottal stops). Before and sometimes after palatal surgery, the speech defect is caused by inadequacies in function of the palatal and pharyngeal muscles. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve that separates the nasopharynx from the oropharynx during swallowing and in the production of certain sounds. If the valve does not function adequately, it is difficult to build up enough pressure in the mouth to make such explosive sounds as p, b, d, t, h, y, or the sibilants s, sh, and ch, and such words as “cats,” “boats,” and “sisters” are not intelligible. After operation or the insertion of a speech appliance, speech therapy is necessary.

VELOPHARYNGEAL DYSFUNCTION

The speech disturbance characteristic of the child with a cleft palate can also be produced by other osseous or neuromuscular abnormalities where there is an inability to form an effective seal between oropharynx and nasopharynx during swallowing or phonation. In a child who has the potential for abnormal speech, adenoidectomy can precipitate overt hypernasality. If the neuromuscular function is adequate, compensation in palatopharyngeal movement might take place and the speech defect might improve, although speech therapy is necessary. In other cases, slow involution of the adenoids can allow gradual compensation in palatal and pharyngeal muscular function. This might explain why a speech defect does not become apparent in some children who have a submucous cleft palate or similar anomaly predisposing to palatopharyngeal incompetence.

Clinical Manifestations

Although clinical signs vary, the symptoms of velopharyngeal dysfunction are similar to those of a cleft palate. There may be hypernasal speech (especially noted in the articulation of pressure consonants such as p, b, d, t, h, v, f, and s); conspicuous constricting movement of the nares during speech; inability to whistle, gargle, blow out a candle, or inflate a balloon; loss of liquid through the nose when drinking with the head down; otitis media; and hearing loss. Oral inspection might reveal a cleft palate or a relatively short palate with a large oropharynx; absent, grossly asymmetric, or minimal muscular activity of the soft palate and pharynx during phonation or gagging; or a submucous cleft.

Bibliography

Many syndromes have distinct or accompanying facial, oral, and dental manifestations (see Apert syndrome, Chapter 591.12; Crouzon disease, Chapter 591.12; Down syndrome, Chapter 81.2).

Osteogenesis imperfecta is often accompanied by effects on the teeth, termed dentinogenesis imperfecta (see Chapter 307, Fig. 307-2). Depending on the severity of presentation, treatment of the dentition varies from routine preventive and restorative monitoring to covering affected posterior teeth with stainless steel crowns, to prevent further tooth loss and improve appearance. Dentinogenesis imperfecta can also occur in isolation without the bony effects.

Another syndrome, cleidocranial dysplasia, has orofacial features such as frontal bossing, hypoplastic maxilla and supernumerary teeth. The primary teeth can be over retained and the permanent teeth remain unerupted. Supernumerary teeth are common, especially in the premolar area. Extensive dental rehabilitation may be needed to correct severe tooth crowding, unerupted and supernumerary teeth.

Ectodermal dysplasias (see Chapter 649) are a heterogeneous group of conditions in which oral manifestations range from little or no involvement (the dentition is completely normal) to cases in which the teeth can be totally or partially absent or malformed. Because alveolar bone does not develop in the absence of teeth, the alveolar processes can be either totally or partially absent, and the resultant overclosure of the mandible causes the lips to protrude. Facial development is otherwise not disturbed. Teeth, when present, can range from normal to small and conical. If aplasia of the buccal and labial salivary glands...
is present, dryness and irritation of the oral mucosa can occur. People with ectodermal dysplasia might need partial or full dentures, even at a very young age. The vertical height between the jaws is thus restored, improving the position of the lips and facial contours as well as restor ing masticatory function.

Pierre Robin syndrome consists of micrognathia usually accompanied by a high arched or cleft palate (Fig. 311-1). The tongue is usually of normal size, but the floor of the mouth is foreshortened. The air passages can become obstructed, particularly on inspiration, usually requiring treatment to prevent suffocation. The infant should be maintained in a prone or partially prone position so that the tongue falls forward to relieve respiratory obstruction. Some patients require tracheostomy. Mandibular distraction procedures in the neonate can improve mandibular size, enhance respiration, and facilitate oral feedings.

Sufficient spontaneous mandibular growth can take place within a few months to relieve the potential airway obstruction. Often the growth of the mandible achieves a normal profile in 4-6 yr. Of children with Pierre Robin syndrome, 30-50% have Stickler syndrome, an autosomal dominant condition that includes other findings such as prominent joints, arthritis, hypotonia, hypermobile joints, mitral valve prolapse, hearing loss, and ocular problems (myopia, glaucoma, cataracts, retinal detachment). Mutations are noted in the genes that produce types II, IX, and XI collagen in many, but not all, patients with Stickler syndrome. Other syndromes are associated with Pierre Robin syndrome including 22Q11.2 deletion syndrome (Velocardio facial syndrome).

Mandibulofacial dysostosis (Treacher Collins syndrome or France schetti syndrome) is an autosomal dominant syndrome that primarily affects the face. The facial appearance varies but is characterized by downward sloping palpebral fissures, colobomas of the lower eyelids, sunken cheekbones, blind fistulas opening between the angles of the mouth and the ears, deformed pinnae, atypical hair growth extending toward the cheeks, receding chin, and large mouth. Facial clefts, abnormalities of the ears, and deafness are common. The mandible is usually hypoplastic; the ramus may be deficient, and the coronoid and condylar processes are flat or even aplastic. The palatal vault may be either high or cleft. Dental malocclusions are common. The teeth may be missing, hypoplastic, or displaced or be in an open bite position. Initially, the primary concern is breathing and feeding problems. Surgery to restore normal structure of the face can be performed, which may include repair of cleft palate, zygomatic and orbit reconstruction, reconstruction of the lower eyelid, external ear reconstruction, and orthognathic surgery.

Hemifacial microsomia presentation can be quite variable but is usually characterized by unilateral hypoplasia of the mandible and can be associated with partial paralysis of the facial nerve, underdeveloped ear, and blind fistulas between the angles of the mouth and the ears. Severe facial asymmetry and malocclusion can develop because of the absence or hypoplasia of the mandibular condyle on the affected side. Congenital condylar deformity tends to increase with age. Early craniofacial surgery may be indicated to minimize the deformity. This disorder can be associated with ocular and vertebral anomalies (oculoauriculo-vertebral spectrum, including Goldenhar syndrome); therefore, radiographs of the vertebrae and ribs should be considered to determine the extent of skeletal involvement.

ETIOLOGY

The development of dental caries depends on interrelationships among the tooth surface, dietary carbohydrates, and specific oral bacteria. Organic acids produced by bacterial fermentation of dietary carbohydrates reduce the pH of dental plaque adjacent to the tooth to a point where demineralization occurs. The initial demineralization appears as an opaque white spot lesion on the enamel, and with progressive loss of tooth mineral, cavitation of the tooth occurs (Fig. 312-1).

The group of microorganisms, mutans streptococci, is associated with the development of dental caries. These bacteria have the ability to adhere to enamel, produce abundant acid, and survive at low pH. Once the enamel surface cavitates, other oral bacteria (lactobacilli) can colonize the tooth, produce acid, and foster further tooth demineralization. Demineralization from bacterial acid production is determined by the frequency of carbohydrate consumption and by the type of carbohydrate. Sucrose is the most cariogenic sugar because one of its by-products during bacterial metabolism is glucan, a polymer that enables bacteria to adhere more readily to tooth structures. Dietary behaviors, such as consuming sweetened beverages in a nursing bottle or frequently consuming sticky candies, increase the cariogenic potential of foods because of the long retention of sugar in the mouth.

EPIDEMIOLOGY

The incidence of dental caries has decreased in developed countries in the past 30 yr but has not decreased and remains highly prevalent among low-income children and children from developing countries. More than half of the children in the United States have dental caries, with most of those having caries primarily in the pits and fissures of the occlusal (biting) surfaces of the molar teeth.

CLINICAL MANIFESTATIONS

Dental caries of the primary dentition usually begins in the pits and fissures. Small lesions may be difficult to diagnose by visual inspection,
but larger lesions are evident as darkened or cavitated lesions on the tooth surfaces (Fig. 312-2). Rampant dental caries in infants and toddlers, referred to as early childhood caries, is the result of early colonization of the child with cariogenic bacteria and the frequent ingestion of sugar, either in the bottle or in solid foods. The carious process in this situation is initiated earlier and consequently can affect the maxillary incisors first and then progress to the molars as they erupt.

The prevalence of early childhood caries is 30-50% in children from low socioeconomic backgrounds and as high as 70% in some Native American groups. Besides high frequency of sugar consumption and colonization with cariogenic bacteria, other enabling factors include low socioeconomic status of the family, other family member with carious teeth, recent immigrant status of the child, and the visual presence of dental plaque on the child’s teeth. Children who develop caries at a young age are known to be at high risk for developing further caries as they get older. Therefore, the appropriate prevention of early childhood caries can result in the elimination of major dental problems in toddlers and less decay in later childhood.

COMPLICATIONS
Left untreated, dental caries usually destroy most of the tooth and invade the dental pulp (pulpitis) and significant pain. Pulpitis can progress to pulp necrosis, with bacterial invasion of the alveolar bone causing a dental abscess (Fig. 312-4). Infection of a primary tooth can disrupt normal development of the successor permanent tooth. In some cases, this process leads to sepsis and infection of the facial space.

TREATMENT
The age at which dental caries occurs is important in dental management. Children younger than 3 yr of age lack the developmental ability...
to cooperate with dental treatment and often require sedation, or general anesthesia to repair carious teeth. After age 4 yr, children can generally cope with dental restorative care with the use of local anesthesia.

Dental treatment, using silver amalgam, plastic composite, or stainless steel crowns, can restore most teeth affected with dental caries. If caries involves the dental pulp, a partial removal of the pulp (pulpotomy) or complete removal of the pulp (pulpectomy) may be required. If a tooth requires extraction, a space maintainer may be indicated to prevent migration of teeth, which subsequently leads to malposition of permanent successor teeth.

Clinical management of the pain and infection associated with untreated dental caries varies with the extent of involvement and the medical status of the patient. Dental infection localized to the dentoalveolar unit can be managed by local measures (extraction, pulpotomy). Oral antibiotics are indicated for dental infections associated with fever, cellulitis, and facial swelling, or if it is difficult to anesthetize the tooth in the presence of inflammation. Penicillin is the antibiotic of choice, except in patients with a history of allergy to this agent. Clindamycin and erythromycin are suitable alternatives. Oral analgesics, such as ibuprofen, are usually adequate for the pain control.

### PREVENTION

Because they are seeing infants and toddlers on a periodicity schedule, physicians have an important role in screening children younger than 3 yr of age for dental caries; providing preventive instructions; applying preventive measures, such as fluoride varnish; and referring the child to a dentist if problems exist.

### Fluoride

The most effective preventive measure against dental caries is communal water supplies with optimal fluoride content. Water fluoridation at the level of 0.7-1.2 mg fluoride per liter (ppm F) was introduced in the United States in the 1940s. Because fluoride from water supplies is now one of several sources of fluoride, the Department of Health and Human Services proposes to not have a fluoride range, but instead to limit the recommendation to the lower limit of 0.7 ppm F. The rationale is to balance the benefits of preventing dental caries with reducing the chance of fluorosis. Children who reside in areas with fluoride-deficient water supplies and are at risk for caries benefit from dietary fluoride supplements (Table 312-1). If the patient uses a private water supply, it is necessary to get the water tested for fluoride levels before prescribing fluoride supplements. To avoid potential overdoses, no fluoride prescription should be written for more than a total of 120 mg of fluoride. However, because of confusion regarding fluoride supplements among practitioners and parents, association of supplements with fluorosis, and lack of parent compliance with the daily administration, supplements may no longer be the first-line approach for preventing caries in preschool-aged children.

Topical fluoride on a daily basis can be achieved by using fluoridated toothpaste. Supervised use of less than a “pea-sized” amount of toothpaste (approximately 0.25 g) on the toothbrush in children younger than 6 yr of age reduces the risk of fluorosis. Children younger than 4 yr of age should brush with less than a “smear or grain-sized” amount of fluoridated toothpaste. Professional topical fluoride applications performed semiannually reportedly reduce caries by approximately 30%. Fluoride varnish is ideal for professional applications in preschool children because of ease of use, even with non–dental health providers, and its safety because of single-dose dispensers. Products that are available now come in containers of 0.25, 0.4, or 0.6 mL of varnish, corresponding to 5.6, 9.0, and 13.6 mg fluoride, respectively. Fluoride varnish should be administered twice a year for preschool children at moderate caries risk and 4 times a year for children at high caries risk.

### Oral Hygiene

Daily brushing, especially with fluoridated toothpaste, helps prevent dental caries. Most children younger than 8 yr of age do not have the coordination required for adequate tooth brushing. Accordingly, parents should assume responsibility for the child’s oral hygiene, with the degree of parental involvement appropriate to the child’s changing abilities.

### Diet

Frequent consumption of sweetened fruit drinks is not generally recognized by parents for its high cariogenic potential. Consuming sweetened beverages in a nursing bottle or sippy cup should be discouraged, and special efforts made to instruct parents that their child should only consume sweetened beverages at meal times and not exceed 6 oz per day.

### Dental Sealant

Plastic dental sealants have been shown to be effective in preventing caries on the pit and fissure of the primary and permanent molars. Sealants are most effective when placed soon after teeth erupt and used in children with deep grooves and fissures in the molar teeth.

Bibliography

The periodontium includes the gingiva, alveolar bone, cementum, and periodontal ligament (see Fig. 312-3).

GINGIVITIS
Poor oral hygiene results in the accumulation of dental plaque at the tooth–gingival interface that activates an inflammatory response, expressed as localized or generalized reddening and swelling of the gingiva. More than half of American school children experience gingivitis. In severe cases, the gingiva spontaneously bleeds and there is oral malodor. Treatment is proper oral hygiene (careful tooth brushing and flossing); complete resolution can be expected. Fluctuations in hormonal levels during the onset of puberty can increase inflammatory response to plaque. Gingivitis in healthy children is unlikely to progress to periodontitis (inflammation of the periodontal ligament resulting in loss of alveolar bone).

AGGRESSIVE PERIODONTITIS IN CHILDREN (PREPUBERTAL PERIODONTITIS)
Periodontitis in children before puberty is a rare disease that often begins between the time of eruption of the primary teeth and the age of 4 or 5 yr. The disease occurs in localized and generalized forms. There is rapid bone loss, often leading to premature loss of primary teeth. It is often associated with systemic problems, including
neutropenia, leukocyte adhesion or migration defects, hypophosphatemia, Papillon-Lefèvre syndrome, leukemia, and histioctosis X. In many cases, however, there is no apparent underlying medical problem. Nonetheless, diagnostic work-ups are necessary to rule out underlying systemic disease.

Treatment includes aggressive professional teeth cleaning, strategic extraction of affected teeth, and antibiotic therapy. There are few reports of long-term successful treatment to reverse bone loss surrounding primary teeth.

**AGGRESSIVE PERIODONTITIS IN ADOLESCENTS (LOCALIZED JUVENILE PERIODONTITIS)**

Aggressive periodontitis in adolescents is characterized by rapid alveolar bone loss, especially around the erupting primary incisors and 1st molars. Overall prevalence in the United States is <1%, but the prevalence among African-Americans is reportedly 2.5%. This form of periodontitis is associated with a strain of *Aggregatibacter (Actinobacillus)* bacteria. In addition, the neutrophils of patients with aggressive periodontitis can have chemotactic or phagocytic defects. If left untreated, affected teeth lose their attachment and can exfoliate. Treatment varies with the degree of involvement. Patients whose disease is diagnosed at onset are usually managed by surgical or nonsurgical debridement in conjunction with antibiotic therapy. Prognosis depends on the degree of initial involvement and compliance with therapy.

**TEETHING**

Teething can lead to intermittent localized discomfort in the area of erupting primary teeth, irritability, low-grade fevers, and excessive salivation; many children have no apparent difficulties. Treatment of symptoms includes oral analgesics and ice rings for the child to “gum.” Similar manifestations can also arise when the 1st permanent molars erupt at about age 6 yr.

**CYCLOSPORINE- OR PHENYTOIN-INDUCED GINGIVAL OVERGROWTH**

The use of cyclosporine to suppress organ rejection or phenytoin for anticonvulsant therapy, and in some cases calcium channel blockers, is associated with generalized enlargement of the gingiva. Phenytoin and its metabolites have a direct stimulatory action on gingival fibroblasts, resulting in accelerated synthesis of collagen. Phenytoin induces less gingival hyperplasia in patients who maintain meticulous oral hygiene.

Gingival hyperplasia occurs in 10-30% of patients treated with phenytoin. Severe manifestations can include gross enlargement of the gingiva, sometimes covering the teeth; edema and erythema of the gingiva; secondary infection, resulting in abscess formation; migration of teeth; and inhibition of exfoliation of primary teeth and subsequent impaction of permanent teeth. Treatment should be directed toward prevention and, if possible, discontinuation of cyclosporine or phenytoin. Patients undergoing long-term treatment with these drugs should receive frequent dental examinations and oral hygiene care. Severe forms of gingival overgrowth are treated by gingivectomy, but the lesion recurs if drug use is continued.

**ACUTE PERICORONITIS**

Acute inflammation of the flap of gingiva that partially covers the crown of an incompletely erupted tooth is common in mandibular permanent molars. Accumulation of debris and bacteria between the gingival flap and tooth precipitates the inflammatory response. A variant of this condition is a gingival abscess caused by entrapment of bacteria because of orthodontic bands or crowns. Trismus and severe pain may be associated with the inflammation. Untreated cases can result in facial space infections and facial cellulitis.

Treatment includes local debridement and irrigation, warm saline rinses, and antibiotic therapy. When the acute phase has subsided, resection of the gingival flap prevents recurrence. Early recognition of the partial impaction of mandibular 3rd molars and their subsequent extraction prevents these areas from developing pericoronitis.
Bibliography
Dental Trauma

Norman Tinanoff

Traumatic oral injuries may be categorized into 3 groups: injuries to teeth, injuries to soft tissue (contusions, abrasions, lacerations, punctures, avulsions, and burns), and injuries to jaw (mandibular and/or maxillary fractures).

INJURIES TO TEETH

Approximately 10% of children between 18 mo and 18 yr of age sustain significant tooth trauma. There appear to be 3 age periods of greatest predilection: toddlers (1-3 yr), usually from falls or child abuse; school-age children (7-10 yr), usually from bicycle and playground accidents; and adolescents (16-18 yr), often the result of fights, athletic injuries, and automobile accidents. Injuries to teeth are more common among children with protruding front teeth. Children with craniofacial abnormalities or neuromuscular deficits are also at increased risk for dental injury. Injuries to teeth can involve the hard dental tissues, the dental pulp (nerve), and injuries to the periodontal structure (surrounding bone and attachment apparatus) (Fig. 314-1 and Table 314-1).

Fractures of teeth may be uncomplicated (confined to the hard dental tissues) or complicated (involving the pulp). Exposure of the pulp results in its bacterial contamination, which can lead to infection and pulp necrosis. Such pulp exposure complicates therapy and can lower the likelihood of a favorable outcome.

The teeth most often affected are the maxillary incisors. Uncomplicated crown fractures are treated by covering exposed dentin and by placing an aesthetic restoration. Complicated crown fractures involving the tooth pulp usually require endodontic therapy (root canal). Crown-root fractures and root fractures usually require extensive
dental therapy. Such injuries in the primary dentition can interfere with normal development of the permanent dentition, and therefore significant injuries of the primary incisor teeth are usually managed by extraction.

Traumatic oral injuries should be referred to a dentist as soon as possible. Even when the teeth appear intact, a dentist should promptly evaluate the patient. Baseline data (radiographs, mobility patterns, responses to specific stimuli) enable the dentist to assess the likelihood of future complications.

**INJURIES TO PERIODONTAL STRUCTURES**

Trauma to teeth with associated injury to periodontal structures that hold the teeth usually manifests as mobile or displaced teeth. Such injuries are more common in the primary than in the permanent dentition. Categories of trauma to the periodontium include concussion, subluxation, intrusive luxation, extrusive luxation, and avulsion.

**Concussion**

Injuries that produce minor damage to the periodontal ligament are termed concussions. Teeth sustaining such injuries are not mobile or displaced but react markedly to percussion (gentle hitting of the tooth with an instrument). This type of injury usually requires no therapy and resolves without complication. Primary incisors that sustain concussion can change color, indicating pulpal degeneration, and should be evaluated by a dentist.

**Subluxation**

Subluxated teeth exhibit mild to moderate horizontal mobility and/or vertical mobility. Hemorrhage is usually evident around the neck of the tooth at the gingival margin. There is no displacement of the tooth. Many subluxated teeth need to be immobilized by splints to ensure adequate repair of the periodontal ligament. Some of these teeth develop pulp necrosis.

**Intrusion**

Intruded teeth are pushed up into their socket, sometimes to the point where they are not clinically visible. Intruded primary incisors can give the false appearance of being avulsed (knocked out). To rule out avulsion, a dental radiograph is indicated (Figs. 314-2 and 314-3).

**Extrusion**

Extrusion injury is characterized by displacement of the tooth from its socket. The tooth is usually displaced to the lingual (tongue) side, with fracture of the wall of the alveolar socket. These teeth need immediate treatment; the longer the delay, the more likely the tooth will be fixed in its displaced position. Therapy is directed at reduction (repositioning the tooth) and fixation (splinting). The pulp of such teeth often becomes necrotic and requires endodontic therapy. Extrusive luxation in the primary dentition is usually managed by extraction because

complications of reduction and fixation can result in problems with development of permanent teeth.

**Avulsion**

If avulsed permanent teeth are replanted as soon as possible after injury, there is a good chance that normal reattachment will follow and the tooth will have a good prognosis. However, if the tooth is in a dry environment for longer than 1 hr, the ligament that holds the tooth in place has little chance for survival and failure (root resorption, ankylosis) is common. Parents confronted with this emergency situation can be instructed to do the following:

- Find the tooth.
- Briefly rinse the tooth. (Do not scrub the tooth. Do not touch the root. After plugging the sink drain, hold the tooth by the crown and rinse it under running tap water.)
- Insert the tooth into the socket. (Gently place it back into its normal position. Do not be concerned if the tooth extrudes slightly. If the parent or child is too apprehensive for replantation of the tooth, the tooth should be placed in cold cow’s milk or other cold isotonic solution.)
- Go directly to the dentist. (In transit, the child should hold the tooth in its socket with a finger. The parent should buckle a seatbelt around the child and drive safely.)

After the tooth is replanted, it must be immobilized to facilitate reattachment; endodontic therapy is always required. The initial signs of complications associated with replantation can appear as early as 1 wk after trauma or as late as several years later. Close dental follow-up is indicated for at least 1 yr.

**PREVENTION**

To minimize the likelihood of dental injuries:

- Every child or adolescent who engages in contact sports should wear a mouth guard, which may be constructed by a dentist or purchased at any athletic goods store.
- Helmets with face guards should be worn by children or adolescents with neuromuscular problems or seizure disorders to protect the head and face during falls.
- Helmets should also be used during biking, skiing, skating, and skateboarding.
- All children or adolescents with protruding incisors should be evaluated by a pediatric dentist or orthodontist.

**ADDITIONAL CONSIDERATIONS**

Children who experience dental trauma might also have sustained head or neck trauma, and therefore neurologic assessment is warranted. Tetanus prophylaxis should be considered with any injury that disrupts the integrity of the oral tissues. The possibility of child abuse should always be considered.

Oropharyngeal Candidiasis
Oropharyngeal infection with Candida albicans (thrush, moniliasis) (see Chapter 234.1) is common in neonates from contact with the organism in the birth canal or breast. The lesions of oropharyngeal candidiasis (OPC) appear as white plaques covering all or part of the oropharyngeal mucosa. These plaques are removable from the underlying surface, which is characteristically inflamed and has pinpoint hemorrhages. The diagnosis is confirmed by direct microscopic examination on potassium hydroxide smears and culture of scrapings from lesions. OPC is usually self-limited in the healthy newborn infant, but topical application of nystatin to the oral cavity of the baby and to the nipples of breastfeeding mothers will hasten recovery.

OPC is also a major problem during myelosuppressive therapy. Systemic candidiasis, a major cause of morbidity and mortality during myelosuppressive therapy, develops almost exclusively in patients who have had prior oropharyngeal, esophageal, or intestinal candidiasis. This observation implies that prevention of OPC should reduce the incidence of systemic candidiasis. The use of oral rinses of 0.2% chlorhexidine solution plus systemic antifungals may be effective in preventing OPC, systemic candidiasis, or candidal esophagitis.

Aphthous Ulcers
The aphthous ulcer (canker sore) is a distinct oral lesion, prone to recurrence; Table 315-1 notes the differential diagnosis. Aphthous ulcers are reported to develop in 20% of the population. Their etiology is unclear, but allergic or immunologic reactions, emotional stress, genetics, and injury to the soft tissues in the mouth have been implicated. Aphthous-like lesions may be associated with inflammatory bowel disease, Behçet disease, gluten-sensitive enteropathy, periodic fever-aphthae-pharyngitis-adenitis syndrome, Sweet syndrome, HIV infection (especially if ulcers are large and slow to heal), and cyclic neutropenia. Clinically, these ulcers are characterized by well-circumscribed, ulcerative lesions with a white necrotic base surrounded by a red halo. The lesions last 10-14 days and heal without scarring. Nonprescription palliative therapies, such as benzocaine and topical lidocaine, are effective, as are topical steroids. Tetracycline has benefit with severe outbreaks, but caution is necessary in pregnant women and young children to prevent tetracycline tooth staining during a child’s tooth development.

Herpetic Gingivostomatitis
After an initial incubation period of approximately 1 wk, the initial infection with herpes simplex virus manifests as fever and malaise, usually in a child younger than 5 yr (see Chapter 252). The oral cavity can show various expressions, including the gingiva becoming erythematous, mucosal hemorrhages, and clusters of small vesicles erupting throughout the mouth. There is often involvement of the mucocutaneous margin and perioral skin (Fig. 315-1). The oral symptoms generally are accompanied by fever, lymphadenopathy, and difficulty eating and drinking. The symptoms usually regress within 2 wk without scarring. Fluids should be encouraged because the child may become dehydrated. Analgesics and anesthetic rinses can make the child more comfortable. Oral acyclovir if taken within the 1st 3 days of symptoms may be beneficial in shortening the duration of
symptoms. Caution should be exercised to prevent autoinoculation or transmission of infection to the eyes.

**RECURRENT HERPES LABIALIS**
Approximately 90% of the population develops antibodies to herpes simplex virus. In periods of quiescence, the virus is thought to remain latent in sensory neurons. Unlike primary herpetic gingivostomatitis, which manifests as multiple painful vesicles on the lips, tongue, palate, gingiva, and mucosa, recurrent herpes is generally limited to the lips. Other than the annoyance of causing pain and an unattractive appearance, there are generally no systemic symptoms. Reactivation of the virus is thought to be the result of exposure to ultraviolet light, tissue trauma, stress, or fevers. There is little advantage of antiviral therapy over palliative therapies in an otherwise healthy patient affected by recurrent herpes.

**BOHN NODULES**
Bohn nodules are small developmental anomalies located along the buccal and lingual aspects of the mandibular and maxillary ridges and in the hard palate of the neonate. These lesions arise from remnants of mucous gland tissue. Treatment is not necessary, because the nodules disappear within a few weeks.

**DENTAL LAMINA CYSTS**
Dental lamina cysts are small cystic lesions located along the crest of the mandibular and maxillary ridges of the neonate. These lesions arise from epithelial remnants of the dental lamina. Treatment is not necessary; they disappear within a few weeks.

**FORDYCE GRANULES**
Almost 80% of adults have multiple yellow-white granules in clusters or plaque-like areas on the oral mucosa, most commonly on the buccal mucosa or lips. They are aberrant sebaceous glands. The glands are present at birth, but they can hypertrophy and first appear as discrete yellowish papules during the preadolescent period in approximately 50% of children. No treatment is necessary.

**CHEILITIS**
This dryness of the lips followed by scaling and cracking and accompanied by a characteristic burning sensation is common in children. Cheilitis may be caused by sensitivity to contact substances, lip licking, vitamin deficiency, weakened immune system, or fungal or bacterial infections. Cheilitis often occurs in association with fever. Treatment may include antifungal or antibacterial agents and frequent application of petroleum jelly.

**ANKYLOGLOSSIA**
Ankyloglossia or “tongue-tie” is characterized by an abnormally short lingual frenum that can hinder the tongue movement but rarely interferes with feeding or speech. The frenum might spontaneously lengthen as the child gets older. If the extent of the ankyloglossia is severe, speech may be affected and surgical correction may be indicated.

**GEOGRAPHIC TONGUE**
Geographic tongue (migratory glossitis) is a benign and asymptomatic lesion and is characterized by 1 or more smooth, bright red patches, often showing a yellow, gray, or white membranous margin on the dorsum of an otherwise normally roughened tongue. The condition has no known cause, and no treatment is indicated (see Chapter 664).

**FISSURED TONGUE**
The fissured tongue (scrotal tongue) is a malformation manifested clinically by numerous small furrows or grooves on the dorsal surface (see Chapter 664). If the tongue is painful, brushing the tongue or irrigating with water can reduce the bacteria in the fissures.
With the exception of mumps (see Chapter 248), disease of the salivary glands is rare in children. Bilateral enlargement of the submaxillary glands can occur in AIDS, cystic fibrosis, Epstein-Barr virus infection, and malnutrition, and, transiently, during acute asthmatic attacks. Chronic vomiting can be accompanied by enlargement of the parotid glands. Benign salivary gland hypertrophy has been associated with endocrinopathies: thyroid disease, diabetes, and Cushing syndrome. Infiltrative disease or tumors are uncommon; red flags include facial nerve palsy, rapid growth, fixed skin, paresthesias, ulceration, or a history of radiation to the head or neck region.

**PAROTITIS**

Acute parotitis is often caused by blockage, with further inflammation due to bacterial infection. The blockage may be due to a salivary stone or mucus plug. Stones can be removed by physical manipulation, surgery, or lithotripsy. Recurrent parotitis is an idiopathic swelling of the parotid gland that can occur in otherwise healthy children. The swelling is usually unilateral, but both glands can be involved simultaneously or alternately. There is little pain; the swelling is limited to the gland and usually lasts 2-3 wk. Treatment may include local heat, massaging the gland, and antibiotics. Suppurative parotitis is usually caused by *Staphylococcus aureus*. It is usually unilateral and may be accompanied by fever. The gland becomes swollen, tender, and painful. Suppurative parotitis responds to antibacterial therapy based on culture obtained from the Stensen duct or by surgical drainage. Viral causes of parotitis include mumps (often in epidemics), EBV, human herpes virus 6, enteroviruses, and HIV.

**RANULA**

A ranula is a cyst associated with a major salivary gland in the sublingual area. It is a large, soft, mucus-containing swelling in the floor of the mouth. It occurs at any age, including infancy. The cyst should be excised, and the severed duct should be exteriorized.

**MUCOCELE**

Mucocoele is a salivary gland lesion caused by a blockage of a salivary gland duct. It is most common on the lower lip and has the appearance of a fluid-filled vesicle or a fluctuant nodule with the overlying mucosa normal in color. Treatment is surgical excision, with removal of the involved accessory salivary gland.

**CONGENITAL LIP PITS**

Congenital lip pits are caused by fistulous tracts that lead to embedded mucous glands in the lower lip. They leak saliva, especially with salivary stimulation. Lip pits can be isolated anomalies, or they can be found in patients with cleft lip or palate. Treatment is surgical excision of the glandular tissue.

**ERUPTION CYST**

Eruption cyst is a smooth, painless swelling over the erupting tooth. If bleeding occurs in the cyst space, it may appear blue or blue-black. In most cases, no treatment is indicated and the cyst resolves with the full eruption of the tooth.

**XEROSTOMIA**

Also known as dry mouth, xerostomia may be associated with fever, dehydration, anticholinergic drugs, chronic graft-versus-host disease, Mikulicz disease (leukemia infiltrates), Sjögren syndrome, or tumoricidal doses of radiation when the salivary glands are within the field. Long-term xerostomia is a high-risk factor for dental caries.

**SALIVARY GLAND TUMORS**

See Chapter 500.

**HISTIOCYTIC DISORDERS**

See Chapter 507.

**TUMORS OF THE JAW**

Ossifying fibroma is a common benign tumor of the jaw. It is often asymptomatic, being discovered on routine radiographic examinations. Treatment is resection because of the possibility of recurrence. Central giant cell granuloma is another common lesion thought to be reactive rather than neoplastic. Although usually asymptomatic, it can be expansile, with or without resorption of the roots of teeth and perforation of the cortical plate. Treatment is complete curettage or surgical excision. Dentigerous cysts are common lesions associated with the crown of an impacted or unerupted tooth. Although usually asymptomatic, they can become large and destructive. Treatment is surgical removal.

The malignant primary tumors of the jaw in children include Burkitt lymphoma, osteogenic sarcoma, lymphosarcoma, ameloblastoma, and, more rarely, fibrosarcoma.

Bibliography
The **panoramic radiograph** provides a single tomographic image of the upper and lower jaw, including all the teeth and supporting structures. The x-ray tube rotates about the patient's head with reciprocal movement of the film or image receptor during the exposure. The panoramic image shows the teeth, mandibular bodies, rami, and condyles; maxillary sinuses; and a majority of the facial buttresses. Such images are used to show abnormalities of tooth number, development and eruption pattern, cystic and neoplastic lesions, bone infections, and fracture, as well as dental caries and periodontal disease (Fig. 317-1).

**Cephalometric radiographs** are posteroanterior and lateral skull films that are taken using a **cephalostat** (head positioner) and employ techniques that clearly demonstrate the facial skeleton and soft facial tissues. Similar protocols for positioning children are used throughout the world. From these images, cranial and facial points and planes can be determined and compared with standards derived from thousands of images. A child's facial growth can be assessed serially when cephalometric radiographs are taken sequentially. Relationships among the maxilla, mandible, cranial base, and facial skeleton can be determined in a quantitative manner. Additionally, the alignment of the teeth and the relation of the teeth to the supporting bone can be serially measured.

**Intraoral dental radiographs** are highly detailed, direct-exposure films that demonstrate sections of the child's teeth and supporting bone structures. The film or image receptor is placed lingual to the teeth,
Figure 317-1 A panoramic radiograph of a 10 yr old child showing extensive dental caries of the 1st permanent molars (arrows), as well as normal structures: erupted 1st permanent molar, unerupted 2nd molar, and unerupted 3rd molar; erupted incisors (EI), unerupted premolars (UP), and erupted primary canines (pc).

and the x-ray beam is directed through the teeth and supporting structures. The resulting images are used to detect dental caries, loss of alveolar bone (periodontal disease), abscesses at the roots of the teeth, and trauma to the teeth and alveolar bone and to demonstrate the developmental status of permanent teeth within the bone.
circulate the amniotic fluid; polyhydramnios is a hallmark of lack of normal swallowing or of esophageal or upper gastrointestinal tract obstruction. Sucking and swallowing are not fully coordinated before 34 wk of gestation, a contributing factor for feeding difficulties in premature infants.

ANATOMY

The luminal aspect of the esophagus is covered by thick, protective, nonkeratinized stratified squamous epithelium, which abruptly changes to simple columnar epithelium at the stomach’s upper margin, at the gastroesophageal junction (GEJ). This squamous epithelium is relatively resistant to damage by gastric secretions (in contrast to the ciliated columnar epithelium of the respiratory tract), but chronic irritation by gastric contents can result in morphometric changes (thickening of the basal cell layer and lengthening of papillary ingrowth into the epithelium) and subsequent metaplasia of the cells lining the lower esophagus from squamous to columnar. Deeper layers of the esophageal wall are composed successively of lamina propria, muscularis mucosae, submucosa, and the 2 layers of muscularis propria (circular surrounded by longitudinal). The 2 delimiting sphincters of the esophagus, the upper esophageal sphincter (UES) at the cricopharyngeus muscle and the LES at the GEJ, constrict the esophageal lumen at its proximal and distal boundaries. The muscularis propria of the upper third of the esophagus is predominantly striated, and that of the lower two-thirds is smooth muscle. Clinical conditions involving striated muscle (cricopharyngeal dysfunction, cerebral palsy) affect the upper esophagus, whereas those involving smooth muscle (achalasia, reflux esophagitis) affect the lower esophagus. The muscular LES and the mucosal “Z-line” of the GEJ may be discrepant up to several centimeters.

FUNCTION

The esophagus can be divided into 3 areas: the UES, the esophageal body, and the LES. At rest, the tonic LES pressure is normally approximately 20 mm Hg; values <10 mm Hg are usually considered abnormal, although it seems that competence against retrograde flow of gastric material is maintained if the LES pressure is >5 mm Hg. The LES pressure rises during intragastric pressure amplifications, whether caused by gastric contractions, abdominal wall muscle contractions (“straining”), or external pressure applied to the abdominal wall. It also rises in response to cholinergic stimuli, gastrin, gastric alkalization, and certain drugs (bethanechol, metoclopramide, cisapride). The UES pressure is more variable and often higher than that of the LES; it decreases almost to zero during deep sleep and it increases markedly during stress and straining. The UES and LES relax briefly to allow material to pass through during swallowing, belching, reflux, and vomiting. They can contract in response to subthreshold levels of reflex (esophagoglottal closure reflex).

Swallowing is initiated by elevation of the tongue, propelling the bolus into the pharynx. The larynx elevates and moves anteriorly, pulling open the relaxing UES, while the opposed aryepiglottic folds close. The epiglottis drops back to cover the larynx and direct the bolus over the larynx and into the UES. The soft palate occludes the nasopharynx. The primary peristalsis thus initiated is a contraction originating in the oropharynx that clears the esophagus aborally (Fig. 318-1). The LES, tonically contracted as a barrier against gastroesophageal reflux (GER), relaxes as swallowing is initiated, at nearly the same time as the UES relaxation. The LES relaxation persists considerably longer, until the peristaltic wave traverses it and closes it. The normal esophageal peristaltic speed is approximately 3 cm/sec; the wave takes 4 sec or longer to traverse the 12 cm esophagus of a young infant and considerably longer in a larger child. Facial stimulation by a puff of air can induce swallowing and esophageal peristalsis in healthy young infants, a reflex termed the Santmyer swallow.

In addition to relaxing to move swallowed material past the GEJ into the stomach, the LES normally relaxes to vent swallowed air or to allow retrograde expulsion of material from the stomach. Perhaps as an extension of these functions, the normal LES also permits physiologic reflux episodes, brief events that occur approximately 5 times in the...
first postprandial hour, particularly in the awake state, but are otherwise uncommon. **Transient LES relaxation**, not associated with swallowing, is the major mechanism underlying **pathologic reflux** (see Fig. 318-1).

The close linkage of the anatomy of the upper digestive and respiratory tracts has mandated intricate functional protections of the respiratory tract during retrograde movement of gastric contents as well as during swallowing. The protective functions include the LES tone, the bolstering of the LES by the surrounding diaphragmatic crura, and the “backup protection” of the UES tone. Secondary peristalsis, akin to primary peristalsis but without an oral component, originates in the upper esophagus, triggered mainly by GER, and thereby also clears refluxed gastric contents from the esophagus. Another protective reflex is the “pharyngeal swallow” (initiated above the esophagus, but without lingual participation). Multiple levels of protection against aspiration include the rhythmic coordination of swallowing and breathing and a series of protective reflexes with esophagopharyngeal afferents and efferents that close the UES or larynx. These reflexes include the esophago-UES contractile reflex, the pharyngo-UES contractile reflex, the esophagolottal closure reflex, and 2 pharyngolottal adduction reflexes. The last 2 reflexes have chemoreceptors on the laryngeal surface of the epiglottis and mechanoreceptors on the aryepiglottic folds as their sites of stimulus. It is likely that interactions between the esophagus and the respiratory tract, which cause extraesophageal manifestations of gastroesophageal reflux disease (GERD), will be explained by subtle abnormalities in these protective reflexes.

**Figure 318-1** A continuous tracing of esophageal motility showing 2 swallows, as indicated by the pharyngeal contraction associated with relaxation of the upper esophageal sphincter (UES) and followed by peristalsis in the body of the esophagus. The lower esophageal sphincter (LES) also displays a transient relaxation (arrow) unassociated with a swallow. There is an episode of gastroesophageal reflux (*) recorded by a pH probe at the time of the transient LES relaxation. (Courtesy of John Dent, FRACP, PhD, and Geoffrey Davidson, MD.)

**318.1 Common Clinical Manifestations and Diagnostic Aids**

**COMMON CLINICAL MANIFESTATIONS**

Manifestations of esophageal disorders include pain, obstruction or difficulty swallowing, abnormal retrograde movement of gastric contents (reflux, regurgitation, or vomiting), or bleeding; esophageal disease can also engender respiratory symptoms. Pain in the chest unrelated to swallowing (heartburn) can be a sign of esophagitis, but similar pain might also represent cardiac, pulmonary, or musculoskeletal disease or visceral hyperalgesia. Pain during swallowing (odynophagia) localizes the disease more discretely to the pharynx and esophagus and often represents inflammatory mucosal disease. Complete esophageal obstruction can be produced acutely by esophageal foreign bodies, including food impactions; can be congenital, as in esophageal atresia; or can evolve over time as a peptic stricture occludes the esophagus. Difficulty swallowing (dysphagia) can be produced by incompletely conclusive esophageal obstruction (by extrinsic compression, intrinsic narrowing, or foreign bodies) but can also result from dysmotility of the esophagus (whether primary/idiopathic or secondary to systemic disease). Inflammatory lesions of the esophagus without obstruction or dysmotility are a third cause of dysphagia; eosinophilic esophagitis, most often afflicting older boys, is relatively common.

The most common esophageal disorder in children is GERD, which is from retrograde return of gastric contents into the esophagus. Esophagitis can be caused by GERD, by eosinophilic disease, by infection, or by caustic substances. Esophageal bleeding can result from severe esophagitis that produces erosions or ulcerations and can manifest as anemia or Hemoccult-positive stools. More acute or severe bleeding can be from ruptured esophageal varices. The resulting hematemesis must be differentiated from more distal bleeding (gastric ulcer) and from more proximal bleeding (a nosebleed or hemoptysis). Respiratory symptoms of esophageal disease can result from luminal contents incorrectly being directed into the respiratory tract or to reflexive respiratory responses to esophageal stimuli.

**DIAGNOSTIC AIDS**

The esophagus can be evaluated by radiography, endoscopy, histology, scintigraphy, manometry, pH-metry (linked as indicated with other polysomnography), and multichannel intraluminal impedance. Contrast (usually barium) radiographic study of the esophagus usually incorporates fluoroscopic imaging over time so that motility and anatomy can be assessed. Although most often requested to evaluate for GERD, it is neither sensitive nor specific for this purpose; it can detect complications of GERD (stricture or hiatal hernia) or conditions mimicking GERD (pyloric stenosis or malrotation with intermittent volvulus).

Barium fluoroscopy is optimal for evaluating for structural anomalies, such as duplications, strictures, or external esophageal compression by an aberrant blood vessel, or for causes of dysmotility, such as achalasia. Modifications of the routine barium fluoroscopic study are used in special situations. When an “H-type” tracheoesophageal fistula is suspected, the test is most sensitive if the radiologist, with the patient prone, distends the esophagus with barium via a nasogastric tube. The videofluoroscopic evaluation of swallowing performed with varying consistencies of barium (“modified barium swallow,” oropharyngeal videofluoroscopy, or “cookie swallow”) optimally evaluates children with dysphagia by demonstrating incoordination of the pharyngeal and esophageal phases of swallowing and any associated aspiration.

In some centers, fiberoptic endoscopic evaluation of swallowing uses nasopharyngeal endoscopy to visualize the pharynx and larynx during swallowing of dye-enhanced foods when dysphagia, laryngeal penetration, or aspiration are suspected. This is often combined with sensory testing of the laryngeal adductor reflex in response to a calibrated puff of air through the endoscope to the arytenoids, generating the composite fiberoptic endoscopic evaluation of swallowing sensory testing.
that examines the mechanisms of any aspiration that is present. Endoscopy allows direct visualization of esophageal mucosa and helps therapeutically in the removal of foreign bodies and treatment of esophageal varices. Endoscopy also allows biopsy samples to be taken, thus improving the diagnosis of “endoscopy-negative” GERD, differentiating GERD from eosinophilic esophagitis, and identifying viral or fungal causes of esophagitis.

Radionuclide scintigraphy scans are helpful in evaluating the efficiency of peristalsis and demonstrating reflux episodes. They can be specific, although not very sensitive, for aspiration and can quantify gastric emptying, thus hinting at a cause for GERD. The related radio-nuclide salivagram can demonstrate aspiration of even minute amounts of saliva.

Esophageal manometry evaluates for dysmotility from the pharynx to the stomach; by synchronized quantitative pressure measurements along the esophagus, it detects and characterizes dysfunctions sometimes missed radiographically. Manometry is often challenging in young infants, and sphincters are optimally evaluated with special Dent sleeves, rather than the simple ports available for the esophageal body.

Extended pH monitoring of the distal esophagus is a sensitive test for acidic GER episodes that can quantify duration and degree of acidity, but not volume, of the reflux episodes. It is linked with polysomnography (a “pneumogram”) when GER is suspected to cause apnea or similar symptoms.

Multichannel intraluminal impedance is a method for pH-independent detection of bolus movements in the esophagus; with a pH probe incorporated, it can distinguish between acid and nonacid liquid and gaseous reflux, the proximal extent of reflux, and several aspects of esophageal function, such as direction of bolus flow, duration of bolus presence, and bolus clearance.
Bibliography

Esophageal atresia (EA) is the most common congenital anomaly of the esophagus, with a prevalence of 1.7 per 10,000 live births. Of these, >90% have an associated tracheoesophageal fistula (TEF). In the most common form of EA, the upper esophagus ends in a blind pouch and the TEF is connected to the distal esophagus (type C). Figure 319-1 shows the types of EA and TEF and their relative frequencies. The exact cause is still unknown; associated features include advanced maternal age, European ethnicity, obesity, low socioeconomic status, and tobacco smoking. This defect has survival rates of >90%, owing largely to improved neonatal intensive care, earlier recognition, and appropriate intervention. Infants weighing <1,500 g at birth and those with severe cardiac anomalies have the highest risk for mortality. Fifty percent of infants are nonsyndromic without other anomalies, and the rest have associated anomalies, most often associated with the VATER or VACTERL (vertebral, anorectal, cardiac, tracheal, esophageal, renal, radial, limb) syndrome. Cardiac and vertebral anomalies are seen in 32% and 24%, respectively. These syndromes generally are associated with normal intelligence. Despite low concordance among twins and the low incidence of familial cases, genetic factors have a role in the pathogenesis of TEF in some patients as suggested by discrete mutations in syndromic cases: Feingold syndrome (N-MYC), CHARGE syndrome (coloboma of the eye, central nervous system anomalies; heart defects; atresia of the choanae; retardation of growth and/or development; genital and/or urinary defects [hypogonadism]; ear anomalies and/or deafness) (CHD7), and anophthalmia-esophageal-genital syndrome (SOX2).

PRESENTATION
The neonate with EA typically has frothing and bubbling at the mouth and nose after birth as well as episodes of coughing, cyanosis, and respiratory distress. Feeding exacerbates these symptoms, causes regurgitation, and can precipitate aspiration. Aspiration of gastric contents via a distal fistula causes more damaging pneumonia than aspiration of pharyngeal secretions from the blind upper pouch. The infant with an isolated TEF in the absence of EA (“H-type” fistula) might come to medical attention later in life with chronic respiratory problems, including refractory bronchospasm and recurrent pneumonias.

DIAGNOSIS
In the setting of early-onset respiratory distress, the inability to pass a nasogastric or orogastric tube in the newborn suggests EA. Perinatal radiographic findings of absence of the infant stomach bubble and maternal polyhydramnios might alert the physician to EA. Plain radiography in the evaluation of respiratory distress might reveal a coiled feeding tube in the esophageal pouch and/or an air-distended stomach, indicating the presence of a coexisting TEF (Fig. 319-2). Conversely, pure EA can manifest as an airless scaphoid abdomen. In isolated TEF (H type), an esophagogram with contrast medium injected under pressure can demonstrate the defect (Fig. 319-3). Alternatively, the orifice may be detected at bronchoscopy or when methylene blue dye injected into the endotracheal tube during endoscopy is observed in the esophagus during forced inspiration.

MANAGEMENT
Initially, maintaining a patent airway, pre-operative proximal pouch decompression to prevent aspiration of secretions and use of antibiotics to prevent consequent pneumonia are paramount. Prone positioning minimizes movement of gastric secretions into a distal fistula, and esophageal suctioning minimizes aspiration from a blind pouch. Endotracheal intubation with mechanical ventilation is to be avoided if possible because it can worsen distention of abdominal viscera. Surgical ligation of the TEF and primary end-to-end anastomosis of the esophagus via right-sided thoracotomy constitute the current standard surgical approach. In the premature or otherwise complicated infant, a primary closure may be delayed by temporizing with fistula ligation and gastrostomy tube placement. If the gap between the atretic ends of the esophagus is >3-4 cm, primary repair cannot be done; options include using gastric, jejunal, or colonic segments interposed as a neoesophagus. Careful search must be undertaken for the common associated cardiac and other anomalies. Thoracoscopic surgical repair is now considered feasible and associated with favorable long-term outcomes.

OUTCOME
The majority of children with EA and TEF grow up to lead normal lives, but complications are often challenging, particularly during the 1st 5 yr of life. Complications of surgery include anastomotic leak, refistulization, and anastomotic stricture. Gastroesophageal reflux
Figure 319-2 Tracheoesophageal fistula. Lateral radiograph demonstrating a nasogastric tube coiled (arrows) in the proximal segment of an atretic esophagus. The distal fistula is suggested by gaseous dilation of the stomach (S) and small intestine. The arrowhead depicts vertebral fusion, whereas a heart murmur and cardiomegaly suggest the presence of a ventricular septal defect. This patient demonstrated elements of the VATER (vertebral, anorectal, tracheal, esophageal, renal, radial) anomaly. (From Balfe D, Ling D, Siegel M: The esophagus. In Putman CE, Ravin CE, editors: Textbook of diagnostic imaging, Philadelphia, 1988, WB Saunders.)

Figure 319-3 H-type fistula (arrow) demonstrated in an infant after barium swallow on frontal-oblique chest x-ray. The tracheal aspect of the fistula is characteristically superior to the esophageal aspect. Barium is seen to outline the tracheobronchial tree. (From Wyllie R, Hyams JS, editors: Pediatric gastrointestinal and liver disease, ed 3, Philadelphia, 2006, Saunders Elsevier, p. 299.)

disease, resulting from intrinsic abnormalities of esophageal function, often combined with delayed gastric emptying, contributes to management challenges in many cases. Gastroesophageal reflux disease contributes significantly to the respiratory disease (reactive airway disease) that often complicates EA and TEF and also worsens the frequent anastomotic strictures after repair of EA.

Many patients have an associated tracheomalacia that improves as the child grows.

319.2 Laryngotracheoesophageal Clefts
Seema Khan and Susan R. Orenstein

Laryngotracheoesophageal clefts are uncommon anomalies that result when the septum between the esophagus and trachea fails to develop fully, leading to a common channel defect between the pharyngo-esophagus and laryngotracheal lumen, thus making the laryngeal closure incompetent during swallowing or reflux. Other developmental anomalies, such as EA and TEF, are seen in 20% of patients with clefts. The severity of presenting symptoms depends on the type of cleft; they are commonly classified as 4 types (I-IV) according to the inferior extent of the cleft. Early in life, the infant presents with stridor, choking, cyanosis, aspiration of feedings, and recurrent chest infections. The diagnosis is difficult and usually requires direct endoscopic visualization of the larynx and esophagus. When contrast radiography is used, material is often seen in the esophagus and trachea. Treatment is surgical repair, which can be complex if the defects are long.

Bibliography
Obstructing lesions classically produce dysphagia to solids earlier and more noticeably than to liquids and can manifest when the infant liquid diet begins to incorporate solids; this is in contrast to dysphagia from dysmotility, in which swallowing of liquids is affected as early as, or earlier than, solids. In most instances of dysphagia, evaluation begins with fluoroscopy, which may include videofluoroscopic evaluation of swallowing, particularly if aspiration is a primary symptom. Secondary studies are often endoscopic if intrinsic obstruction is suspected or manometric if dysmotility is suspected; other imaging studies may be used in particular cases. Congenital lesions can require surgery, whereas
webs and peptic strictures might respond adequately to endoscopic (or bougie) dilation. Peptic strictures, once dilated, should prompt consideration of fundoplication for ongoing prophylaxis.

**EXTRINSIC**

Esophageal duplication cysts are the most commonly encountered foregut duplications. These cysts are lined by intestinal epithelium, have a well-developed smooth muscle wall, and are attached to the normal gastrointestinal tract. Most of these affect the distal half of the esophagus on the right side. The most common presentation is respiratory distress caused by compression of the adjacent airways. Dysphagia is a common symptom in older children. Upper gastrointestinal bleeding can occur as a result of acid-secreting gastric mucosa in the duplication wall. Neuroenteric cysts might contain glial elements and are associated with vertebral anomalies. Diagnosis is made using modalities, such as barium swallow, chest CT, and MRI, or endosonography. Treatment is surgical; laparoscopic approach to excision is also possible.

Enlarged mediastinal or subcarinal lymph nodes, caused by infection (tuberculosis, histoplasmosis) or neoplasm (lymphoma), are the most common external masses that compress the esophagus and produce obstructive symptoms. Vascular anomalies can also compress the esophagus; *dysphagia lusoria* is a term denoting the dysphagia produced by a developmental vascular anomaly, which is often an aberrant right subclavian artery or right-sided or double aortic arch (see Chapter 432.1).

**INTRINSIC**

Intrinsic narrowing of the esophageal lumen can be congenital or acquired. The etiology is suggested by the location, the character of the lesion, and the clinical situation. The lower esophagus is the most common location for peptic strictures, which are generally somewhat ragged and several cm long. Thin membranous rings, including the Schatzki ring at the squamocolumnar junction, can also occlude this area. In the midesophagus, congenital narrowing may be associated with the esophageal atresia–tracheoesophageal fistula complex, in which some of the lesions might incorporate cartilage and might be impossible to dilate safely; alternatively, reflux esophagitis can induce a ragged and extensive narrowing that appears more proximal than the usual peptic stricture, often because of an associated hiatal hernia. Congenital webs or rings can narrow the upper esophagus. The upper esophagus can also be narrowed by an inflammatory stricture occurring after a caustic ingestion or due to epidermolysis bullosa. Cricopharyngeal achalasia can appear radiographically as a cricopharyngeal “bar” posteriorly in the upper esophagus. Eosinophilic esophagitis is one of the most common causes for esophageal obstructive symptoms. Although the pathogenesis of obstructive eosinophilic esophagitis is not yet completely explained and seems to vary among individual patients, endoscopy or radiology demonstrates stricture formation in some children with eosinophilic esophagitis, and in others a noncompliant esophagus is evident, with thickened wall layers demonstrable by ultrasonography.

Chapter 321  ◆ Dysmotility  1785

Dysmotility
Seema Khan and Susan R. Orenstein

UPPER ESOPHAGEAL AND UPPER ESOPHAGEAL SPHINCTER DYSMOTILITY (STRIATED MUSCLE)
Cricopharyngeal achalasia signifies a failure of complete relaxation of the upper esophageal sphincter (UES), whereas cricopharyngeal incoordination occurs in infancy and remits spontaneously in the 1st yr of life if nutrition is maintained despite the dysphagia. In children, treatment options for non–self-limited cricopharyngeal achalasia consist of dilation, botox injection, and transcervical myotomy. It is important to evaluate such children thoroughly, including cranial MRI to detect Arnold-Chiari malformations, which can manifest in this way but are best treated by cranial decompression, rather than esophageal surgery. Cricopharyngeal spasm may be severe enough to produce posterior pharyngeal (Zenker) diverticulum above the obstructive sphincter; this entity occurs rarely in children.

Systemic causes of swallowing dysfunction that can affect the oropharynx, UES, and upper esophagus include cerebral palsy, Arnold-Chiari malformations, syringomyelia, bulbar palsy or cranial nerve defects ( Möbius syndrome, transient infantile paralysis of the superior laryngeal nerve), transient pharyngeal muscle dysfunction, spinal muscular atrophy (including Werdnig-Hoffmann disease), muscular dystrophy, multiple sclerosis, infections (botulism, tetanus, poliomyelitis, diphtheria), inflammatory and autoimmune diseases (dermatomyositis, myasthenia gravis, polynuernitits, scleroderma), and familial dysautonomia. All of these can produce dysphagia. Medications (nitrazepam, benzodiazepines) and tracheostomy can adversely affect the function of the UES and thereby produce dysphagia.

LOWER ESOPHAGEAL AND LOWER ESOPHAGEAL SPHINCTER DYSFUNCTION (SMOOTH MUSCLE)
Causes of dysphagia resulting from more distal primary esophageal dysmotility include achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive lower esophageal sphincter (LES); all but achalasia are rare in children. Secondary causes include Hirschsprung disease, pseudoobstruction, inflammatory myopathies, scleroderma, and diabetes.

Achalasia is a primary esophageal motor disorder of unknown etiology characterized by loss of LES relaxation and loss of esophageal peristalsis, both contributing to a functional obstruction of the distal esophagus. Degenerative, autoimmune (antibodies to Auerbach plexus), and infectious (Chagas disease caused by Trypanosoma cruzi) factors are possible causes. In rare cases, achalasia is familial or part of the achalasia, alacrima, and adrenal insufficiency, known as triple A syndrome or Allgrove syndrome. Pseudoachalasia refers to achalasia caused by various forms of cancer via obstruction of the gastroesophageal junction, infiltration of the submucosa and muscularis of the LES, or as part of the paraneoplastic syndrome with formation of anti-Hu antibodies. Pathologically, in achalasia, inflammation surrounds ganglion cells, which are decreased in number. There is selective loss of postganglionic inhibitory neurons that normally lead to sphincter relaxation, leaving postganglionic cholinergic neurons unopposed. This imbalance produces high basal LES pressures and insufficient LES relaxation. The loss of esophageal peristalsis can be a secondary phenomenon.

Achalasia manifests with regurgitation and dysphagia for solids and liquids and may be accompanied by undernutrition or chronic cough; retained esophageal food can produce esophagitis. The presentations of chronic regurgitation/vomiting with weight loss, and chronic cough have led to misdiagnoses of anorexia nervosa and asthma, respectively. The mean age in children is 8.8 yr, with a mean duration of symptoms before diagnosis of 23 mo; it is uncommon before school age. Chest radiograph shows an air–fluid level in a dilated esophagus. Barium fluoroscopy reveals a smooth tapering of the lower esophagus leading to the closed LES, resembling a bird’s beak (Fig. 321-1). Loss of primary peristalsis in the distal esophagus with retained food and poor emptying are often present. Manometry is the most sensitive diagnostic test; it reveals the defining features of aperistalsis in the...
distal esophageal body and incomplete or absent LES relaxation, often accompanied by high pressure LES and low-amplitude esophageal body contractions.

The goals of achalasia therapy are relief of symptoms, improvement of esophageal emptying, and prevention of megaesophagus. The 2 most effective treatment options are pneumatic dilation and laparoscopic or surgical (Heller) myotomy. Pneumatic dilation is the initial treatment of choice, and does not preclude a future myotomy. Surgeons often supplement a myotomy with an antireflux procedure to prevent the gastroesophageal reflux disease that otherwise often ensues when the sphincter is rendered less competent. Laparoscopic myotomy is a particularly effective procedure in adolescent and young adult males. Peroral endoscopic myotomy may be a feasible, safe, and an effective alternative to the laparoscopic method. Calcium channel blockers (nifedipine) and phosphodiesterase inhibitors offer temporary relief of dysphagia. Endoscopic injection of the LES with botulinum toxin counterbalances the selective loss of inhibitory neurotransmitters by inhibiting the release of acetylcholine from nerve terminals and may be an effective therapy. Botulinum toxin is effective in 50–65% of patients and is expensive; half the patients might require a repeat injection within 1 yr. Most eventually require dilation or surgery.

Diffuse esophageal spasm causes chest pain and dysphagia and affects adolescents and adults. It is diagnosed manometrically and can be treated with nitrates or calcium-channel-blocking agents.

Gastroesophageal reflux disease constitutes the most common cause of nonspecific abnormalities of esophageal motor function, probably through the effect of the esophageal inflammation on the musculature.

Bibliography

Herniation of the stomach through the esophageal hiatus can occur as a common sliding hernia (type 1), in which the gastroesophageal junction slides into the thorax, or it can be paraesophageal (type 2), in which a portion of the stomach (usually the fundus) is insinuated next to the esophagus inside the gastroesophageal junction in the hiatus (Figs. 322-1 and 322-2). A combination of sliding and paraesophageal types (type 3) is present in some patients. Sliding hernias are often associated with gastroesophageal reflux, especially in developmentally delayed children. The relationship to hiatal hernias in adults is unclear. Diagnosis is usually made by an upper gastrointestinal series and upper endoscopy. Medical treatment is not directed at the hernia but at the gastroesophageal reflux, unless failure of medical therapy prompts correction of the hernia at the time of fundoplication.

A paraesophageal hernia can be an isolated congenital anomaly or associated with gastric volvulus, or it may be encountered after fundoplication for gastroesophageal reflux, especially if the edges of a dilated esophageal diaphragmatic hiatus have not been approximated. Fullness after eating and upper abdominal pain are the usual symptoms. Infarction of the herniated stomach is rare.

**Figure 322-1** Types of esophageal hiatal hernia. A, Sliding hiatal hernia, the most common type. B, Paraesophageal hiatal hernia.

**Figure 322-2** A, An upper gastrointestinal series shows a large hiatal hernia that extends above the diaphragm and impedes the exit of contrast from the esophagus into the stomach. Contrast is also noted to reflux to the upper esophagus. B, A retroflexed view of the hernia from the stomach during an upper endoscopy.
**Chapter 323**

**Gastroesophageal Reflux Disease**

Seema Khan and Susan R. Orenstein

Gastroesophageal reflux disease (GERD) is the most common esophageal disorder in children of all ages. Gastroesophageal reflux (GER) signifies the retrograde movement of gastric contents across the lower esophageal sphincter (LES) into the esophagus, which occurs physiologically every day in all infants, older children, and adults. Physiologic GER is exemplified by the effortless regurgitation of normal infants. The phenomenon becomes pathologic GERD in infants and children who manifest or report bothersome symptoms because of frequent or persistent GER, producing esophagitis-related symptoms, or extraesophageal presentations, such as respiratory symptoms or nutritional effects.

**PATHOPHYSIOLOGY**

Factors determining the esophageal manifestations of reflux include the duration of esophageal exposure (a product of the frequency and duration of reflux episodes), the causality of the refluxate, and the susceptibility of the esophagus to damage. The LES, defined as a high-pressure zone by manometry, is supported by the crura of the diaphragm at the gastroesophageal junction, together with valve-like functions of the esophagogastric junction anatomy, form the antireflux barrier. In the context of even the normal intraabdominal pressure augmentations that occur during daily life, the frequency of reflux episodes is increased by insufficient LES tone, by abnormal frequency of LES relaxations, and by hiatal herniation that prevents the LES pressure from being proportionately augmented by the crura during abdominal straining. Normal intraabdominal pressure augmentations may be further exacerbated by straining or respiratory efforts. The duration of reflux episodes is increased by lack of swallowing (e.g., during sleep) and by defective esophageal peristalsis. Vicious cycles ensue because chronic esophagitis produces esophageal peristaltic dysfunction (low-amplitude waves, propagation disturbances), decreased LES tone, and inflammatory esophageal shortening that induces hiatal herniation, all worsening reflux.

**Transient LES relaxation (TLESR)** is the primary mechanism allowing reflux to occur, and is defined as simultaneous relaxation of both LES and the surrounding crura. TLESRs occur independent of swallowing, reduce LES pressure to 0-2 mm Hg (above gastric), and last 10-60 sec; they appear by 26 wk of gestation. A vagovagal reflex, composed of afferent mechanoreceptors in the proximal stomach, a brainstem pattern generator, and efferents in the LES, regulates TLESRs. Gastric distention (postprandially, or from abnormal gastric emptying or air swallowing) is the main stimulus for TLESRs. Whether GERD is caused by a higher frequency of TLESRs or by a greater incidence of reflux during TLESRs is debated; each is likely in different persons. Straining during a TLESR makes reflux more likely, as do positions that place the gastroesophageal junction below the air–fluid interface in the stomach. Other factors influencing gastric pressure–volume dynamics, such as increased movement, straining, obesity, large-volume or hyperosmolar meals, gastroparesis, a large sliding hiatal hernia, and increased respiratory effort (coughing, wheezing) can have the same effect.

**Epidemiology and Natural History**

Infant reflux becomes evident in the 1st few mo of life, peaks at 4 mo, and resolves in up to 88% by 12 mo and in nearly all by 24 mo. Symptoms in older children tend to be chronic, waxing and waning, but completely resolving in no more than half, which resembles adult patterns (Table 323-1). The histologic findings of esophagitis persist in infants who have naturally resolving symptoms of reflux. GERD likely has genetic predispositions: family clustering of GERD symptoms, endoscopic esophagitis, hiatal hernia, Barrett esophagus, and adenocarcinoma have been identified. As a continuously variable and common disorder, complex inheritance involving multiple genes and environmental factors is likely. Genetic linkage is indicated by the strong evidence of GERD in studies with monozygotic twins. A pediatric autosomal dominant form with otolaryngologic and respiratory manifestations has been located to chromosome 13q14, and the locus is termed GERD1.

**Clinical Manifestations**

Most of the common clinical manifestations of esophageal disease can signify the presence of GERD and are generally thought to be mediated by the pathogenesis involving acid GER (Table 323-2). Although less noxious for the esophageal mucosa, nonacid reflux events are recognized to play an important role in extraesophageal disease manifestations. **Infantile reflux** manifests more often with regurgitation (especially postprandially), signs of esophagitis (irritability, arching, choking, gagging, feeding aversion), and resulting failure to thrive; symptoms resolve spontaneously in the majority of infants by 12-24 mo. **Older children** can have regurgitation during the preschool years; this complaint diminishes somewhat as children age, and complaints of abdominal and chest pain supervene in later childhood and adolescence. Occasional children present with food refusal or neck contortions (arching, turning of head) designated **Sandifer syndrome**. The respiratory presentations are also age dependent: GERD in infants can manifest as obstructive apnea or as stridor or lower airway disease in which reflux complicates primary airway disease such as laryngomalacia or bronchopulmonary dysplasia. Otitis media, sinusitis, lymphoid hyperplasia, hoarseness, vocal cord nodes, and laryngeal edema have all been associated with GERD. Airway manifestations in older children are more commonly related to asthma or to otolaryngologic disease such as laryngitis or sinusitis. Despite the high prevalence of GERD symptoms in asthmatic children, data showing direction of causality are conflicting.

**Diagnosis**

For most of the typical GERD presentations, particularly in older children, a thorough history and physical examination suffice initially to reach the diagnosis. This initial evaluation aims to identify the pertinent positives in support of GERD and its complications and the negatives that make other diagnoses unlikely. The history may be facilitated and standardized by questionnaires (e.g., the Infant Gastroesophageal Reflux Questionnaire, the I-GERQ, and its derivative, the I-GERQ-R), which also permit quantitative scores to be evaluated for their diagnostic discrimination and for evaluative assessment of improvement or worsening of symptoms. The clinician should be alerted to the possibility of other important diagnoses in the presence of any alarm or warning signs: bilious emesis, frequent projectile emesis, gastrointestinal bleeding, lethargy, organomegaly, abdominal distention, micro- or macrocephaly, hepatosplenomegaly, failure to thrive, diarrhea, fever, bulging fontanelle, and seizures. The important differential diagnoses to consider in the evaluation of an infant or a child with chronic vomiting are milk and other food allergies, eosinophilic esophagitis, pyloric stenosis, intestinal obstruction (especially malrotation with intermittent volvulus), nongastroesophageal inflammatory diseases, infections, inborn errors of metabolism, hydronephrosis, increased intracranial pressure, ruminations, and bulimia. Focused diagnostic testing, depending on the presentation and the differential diagnosis, can then supplement the initial examination.

Most of the esophageal tests are of some use in particular patients with suspected GERD. **Contrast (usually barium) radiographic** study of the esophagus and upper gastrointestinal tract is performed in children with vomiting and dysphagia to evaluate for achalasia, esophageal strictures and stenosis, hiatal hernia, and gastric outlet or intestinal obstruction (Fig. 323-1). It has poor sensitivity and specificity in the diagnosis of GERD as a result of its limited duration and the inability
biopsies can diagnose histologic reflux esophagitis in the absence of erosions while simultaneously eliminating allergic and infectious causes. Endoscopy is also used therapeutically to dilate reflux-induced strictures. Radionucleotide scintigraphy using technetium can demonstrate aspiration and delayed gastric emptying when these are suspected.

The multichannel intraluminal impedance is a cumbersome test, but with potential applications both for diagnosing GERD and for understanding esophageal function in terms of bolus flow, volume clearance, and (in conjunction with manometry) motor patterns associated with GERD. Owing to the multiple sensors and a distal pH sensor, it is possible to document acidic reflux ($\text{pH} < 4$), weakly acidic reflux ($4 \leq \text{pH} \leq 7$), and weakly alkaline reflux ($\text{pH} > 7$) with multichannel intraluminal impedance. It is an important tool in those with respiratory symptoms, particularly for the determination of nonacid reflux, but must be cautiously applied in routine clinical evaluation because of limited evidence-based parameters for GERD diagnosis and symptom association.

Laryngotracheobronchoscopy evaluates for visible airway signs that are associated with extraesophageal GERD, such as posterior laryngeal inflammation and vocal cord nodules; it can permit diagnosis of silent aspiration (during swallowing or during reflux) by bronchoalveolar lavage with subsequent quantification of lipid-laden macrophages in airway secretions. Detection of pepsin in tracheal fluid is a
to differentiate physiologic GER from GERD. Furthermore, contrast radiography neither accurately assesses mucosal inflammation nor correlates with severity of GERD.

Extended esophageal pH monitoring of the distal esophagus, no longer considered the sine qua non of a GERD diagnosis, provides a quantitative and sensitive documentation of acidic reflux episodes, the most important type of reflux episodes for pathologic reflux. The distal esophageal pH probe is placed at a level corresponding to 87% of the nares-LES distance, based on regression equations using the patient's height, on fluoroscopic visualization, or on manometric identification of the LES. Normal values of distal esophageal acid exposure ($\text{pH} < 4$) are generally established as $<5-8\%$ of the total monitored time, but these quantitative normals are insufficient to establish or disprove a diagnosis of pathologic GERD. The most important indications for esophageal pH monitoring are for assessing efficacy of acid suppression during treatment, evaluating apneic episodes in conjunction with a pneumogram and perhaps impedance, and evaluating atypical GERD presentations such as chronic cough, stridor, and asthma. Dual pH probes, adding a proximal esophageal probe to the standard distal one, are used in the diagnosis of extraesophageal GERD, identifying upper esophageal acid exposure times of 1% of the total time as threshold values for abnormality.

Endoscopy allows diagnosis of erosive esophagitis (Fig. 323-2) and complications such as strictures or Barrett esophagus; esophageal

marker of reflux-associated aspiration of gastric contents. Esophageal manometry permits evaluation for dysmotility, particularly in preparation for antireflux surgery.

**Empirical antireflux therapy**, using a time-limited trial of high-dose proton pump inhibitor (PPI), is a cost-effective strategy for diagnosis in adults; although not formally evaluated in older children, it has also been applied to this age group. Failure to respond to such empirical treatment, or a requirement for the treatment for prolonged periods, mandates formal diagnostic evaluation.

**MANAGEMENT**

Conservative therapy and lifestyle modifications that form the foundation of GERD therapy can be effectively implemented through education and reassurance for parents. Dietary measures for infants include normalization of any abnormal feeding techniques, volumes, and frequencies. Thickening of feeds or use of commercially prethickened formulas increases the percentage of infants with no regurgitation, decreases the frequency of daily regurgitation and emesis, and increases

avoid acidic or reflux-inducing foods (tomatoes, chocolate, mint) and beverages (juices, carbonated and caffeinated drinks, alcohol). Weight reduction for obese patients and elimination of smoke exposure are other crucial measures at all ages.

Positioning measures are particularly important for infants, who cannot control their positions independently. Seated position worsens infant reflux and should be avoided in infants with GERD. Esophageal pH monitoring demonstrates more reflux episodes in infants in supine and side positions compared with the prone position, but evidence that the supine position reduces the risk of sudden infant death syndrome has led the American Academy of Pediatrics and the North American Society of Pediatric Gastroenterology and Nutrition to recommend supine positioning during sleep. When the infant is awake and observed, prone position and upright carried position can be used to minimize reflux. Lying in the flat supine position and semi-seated positions (e.g., car seats, infant carriers) in the postprandial period are considered provocative positions for GER and therefore should be avoided. The efficacy of positioning for older children is unclear, but some evidence suggests a benefit to left side position and head elevation during sleep. The head should be elevated by elevating the head of the bed, rather than using excess pillows, to avoid abdominal flexion and compression that might worsen reflux.

Pharmacotherapy is directed at ameliorating the acidity of the gastric contents or at promoting their aboral movement, and should be considered for those symptomatic infants and children who are either highly suspected or proven to have GERD. Antacids are the most commonly used antireflux therapy and are readily available over the counter. They provide rapid but transient relief of symptoms by neutralizing gastric contents or at promoting their aboral movement, and should be considered provocative positions for GER and therefore should be avoided. The efficacy of positioning for older children is unclear, but some evidence suggests a benefit to left side position and head elevation during sleep. The head should be elevated by elevating the head of the bed, rather than using excess pillows, to avoid abdominal flexion and compression that might worsen reflux.

Histamine-2 receptor antagonists (H2RAs: cimetidine, famotidine, nizatidine, and ranitidine) are widely used antisecretory agents that act by selective inhibition of histamine receptors on gastric parietal cells. There is a definite benefit of H2RAs in treatment of mild-to-moderate reflux esophagitis. H2RAs have been recommended as first-line therapy because of their excellent overall safety profile, but they are superseded by PPIs in this role, as increased experience with pediatric use and safety, FDA approval, and pediatric formulations and dosing are available.

PPIs (omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole) provide the most potent antireflux effect by blocking the hydrogen–potassium adenosine triphosphatase channels of the final common pathway in gastric acid secretion. PPIs are superior to H2RAs in the treatment of severe and erosive esophagitis. Pharmacodynamic studies indicate that children require higher doses of PPIs than adults on a per-weight basis. The use of PPIs to treat infants and children deemed to have GERD on the basis of symptoms is now the standard of care. An important systematic review of the efficacy and safety of PPI therapy in pediatric GERD reveals no clear benefit for PPI over placebo use in suspected infantile GERD (crying, arching behavior). Limited pediatric data are available to draw definitive conclusions about potential complications implicated with PPI use, such as respiratory infections, Clostridium difficile infection, bone fractures (noted in adults), and hypomagnesemia.

Prokinetic agents available in the United States include metoclopramide (dopamine-2 and 5-HT3 antagonist), bethanechol (cholinergic agonist), and erythromycin (motilin receptor agonist). Most of these increase LES pressure; some improve gastric emptying or esophageal clearance. None affects the frequency of TLESRs. The available controlled trials have not demonstrated much efficacy for GERD. In 2009, the FDA announced a black box warning for metoclopramide, linking its chronic use (longer than 3 mo) with tardive dyskinesia, the rarely reversible movement disorder. Baclofen is a centrally acting γ-aminobutyric acid agonist that decreases reflux by decreasing TLESRs in healthy adults and in a small number of neurologically impaired children with GERD. New agents of great interest include peripherally acting γ-aminobutyric acid agonists devoid of central side effects, and metabotropic glutamate receptor 5 antagonists that are reported to reduce TLESRs but are as yet inadequately studied for this indication in children.

Surgery, usually fundoplication, is effective therapy for intractable GERD in children, particularly those with refractory esophagitis or strictures and those at risk for significant morbidity from chronic pulmonary disease. It may be combined with a gastrostomy for feeding or venting. The availability of potent acid-suppressing medication mandates more-rigorous analysis of the relative risks (or costs) and benefits of this relatively irreversible therapy in comparison to long-term pharmacotherapy. Some of the risks of fundoplication include a wrap that is “too tight” (producing dysphagia or gas-bloat) or “too loose” (and thus incompetent). Surgeons may choose to perform a “tight” (360 degrees, Nissen) or variations of a “loose” (<360 degrees, Thal, Toupet, Boix-Ochoa) wrap, or to add a gastric drainage procedure (pyloroplasty) to improve gastric emptying, based on their experience and the patient’s disease. Preoperative accuracy of diagnosis of GERD and the skill of the surgeon are 2 of the most important predictors of successful outcome. Long-term studies suggest that fundoplications often become incompetent in children, as in adults, with reflux recurrence rates of up to 14% for Nissen and up to 20% for loose wraps; this fact currently combines with the potency of PPI therapy that is now available to shift practice toward long-term pharmacotherapy in many cases. Fundoplication procedures may be performed as open operations, by laparoscopy, or by endoluminal (gastroplication) techniques. Pediatric experience is limited with endoscopic application of radiofrequency therapy (Stretta procedure) to a 2-3 cm area of the LES and cardia to create a high-pressure zone to reduce reflux.

ESOPHAGEAL: ESOPHAGITIS AND SEQUELAE—STRUCTURE, BARRETT ESOPHAGUS, ADENOCARCINOMA

Esophagitis can manifest as irritability, arching, and feeding aversion in infants; chest or epigastric pain in older children; and, rarely, as hematemesis, anemia, or Sandifer syndrome at any age. Erosive esophagitis is found in approximately 12% of children with GERD symptoms and is more common in boys, older children, neurologically abnormal children, children with severe chronic respiratory disease, and in those with hiatal hernia. Prolonged and severe esophagitis leads to formation of strictures, generally located in the distal esophagus, producing dysphagia, and requiring repeated esophageal dilations and often fundoplication. Long-standing esophagitis predisposes to metaplastic transformation of the normal esophageal squamous epithelium into intestinal columnar epithelium, termed Barrett esophagus, a precursor of esophageal adenocarcinoma. A large multicenter prospective study of 840 consecutive children who underwent elective endoscopies reported a 25.7% prevalence for reflux esophagitis, and a mere 0.12% for Barrett esophagus in children without neurologic disorders or tracheoesophageal anomalies. Both Barrett esophagus and adenocarcinoma occur more in white males and in those with increased duration, frequency, and severity of reflux symptoms. This transformation increases with age to plateau in the 5th decade; adenocarcinoma is thus rare in childhood. Barrett esophagus, uncommon in children, warrants periodic surveillance biopsies, aggressive pharmacotherapy, and fundoplication for progressive lesions.

NUTRITIONAL

Esophagitis and regurgitation may be severe enough to induce failure to thrive because of caloric deficits. Enteral (nasogastric or nasojejunlal, or percutaneous gastric or jejunal) or parenteral feedings are sometimes required to treat such deficits.
Bibliography

EXTRAESOPHAGEAL: RESPIRATORY ("ATYPICAL") PRESENTATIONS

GERD should be included in the differential diagnosis of children with unexplained or refractory otolaryngologic and respiratory complaints. GERD can produce respiratory symptoms by direct contact of the refluxed gastric contents with the respiratory tract (aspiration, laryngeal penetration, or microaspiration) or by reflexive interactions between the esophagus and respiratory tract (inducing laryngeal closure or bronchospasm). Often, GERD and a primary respiratory disorder, such as asthma, interact and a vicious cycle between them worsens both diseases. Many children with these extraesophageal presentations do not have typical GERD symptoms, making the diagnosis difficult. These atypical GERD presentations require a thoughtful approach to the differential diagnosis that considers a multitude of primary otolaryngologic (infections, allergies, postnasal drip, voice overuse) and pulmonary (asthma, cystic fibrosis) disorders. Therapy for the GERD must be more intense (usually incorporating a PPI) and prolonged (usually at least 3-6 mo). Subspecialist assistance from the perspective of the airway disease (otolaryngology, pulmonology) and the reflux disease (gastroenterology) is often warranted for specialized diagnostic testing and for optimizing intensive management.

APNEA AND STRIDOR

These upper airway presentations have been linked with GERD in case reports and epidemiologic studies; temporal relationships between them and reflux episodes have been demonstrated in some patients by esophageal pH–multichannel intraluminal impedance studies, and a beneficial response to therapy for GERD provides further support in a number of case series. An evaluation of 1,400 infants with apnea attributed the apnea to GERD in 50%, but other studies have failed to find an association. Apnea and apparent life-threatening event caused by reflux is generally obstructive, owing to laryngospasm that may be conceived of as an abnormally intense protective reflex. At the time of such apnea, infants have often been provocatively positioned (supine or flexed seated), have been recently fed, and have shown signs of obstructive apnea, with unproductive respiratory efforts. The evidence suggests that for the large majority of infants presenting with apnea and an apparent life-threatening event, GERD is not causal. Stridor triggered by reflux generally occurs in infants anatomically predisposed toward stridor (laryngomalacia, micrognathia). Spasmodic croup, an episodic frightening upper airway obstruction, can be an analogous condition in older children. Esophageal pH probe studies might fail to demonstrate linkage of these manifestations with reflux owing to the buffering of gastric contents by infant formula and the episodic nature of the conditions. Pneumograms can fail to identify apnea if they are not designed to identify obstructive apnea by measuring nasal airflow.

Reflux laryngitis and other otolaryngologic manifestations (also known as laryngopharyngeal reflux) can be attributed to GERD. Hoarseness, voice fatigue, throat clearing, chronic cough, pharyngitis, sinusitis, otitis media, and a sensation of globus have been cited. Laryngopharyngeal signs of GERD include edema and hyperemia (of the posterior surface), contact ulcers, granulomas, polyps, subglottic stenosis, and interarytenoid edema. The paucity of well-controlled evaluations of the association contributes to the skepticism with which these associations may be considered. Other risk factors irritating the upper respiratory passages can predispose some patients with GERD to present predominantly with these complaints.

Many studies have reported a strong association between asthma and reflux as determined by history, pH–multichannel intraluminal impedance, endoscopy, and esophageal histology. GERD symptoms are present in an average of 23% (19-80%) of children with asthma as observed in a systematic review of 19 studies examining the prevalence of GERD in asthmatics. The review also reported abnormal pH results in 63%, and esophagitis in 35% of asthmatic children. However, this association does not clarify the direction of causality in individual cases and thus does not indicate which patients with asthma are likely to benefit from anti-GERD therapy. Children with asthma who are particularly likely to have GERD as a provocative factor are those with symptoms of reflux disease, those with refractory or steroid-dependent asthma, and those with nocturnal worsening of asthma. Endoscopic evaluation that discloses esophageal sequelae of GERD provides an impetus to embark on the aggressive (high dose and many months’ duration) therapy of GERD.

Dental erosions constitute the most common oral lesion of GERD, the lesions being distinguished by their location on the lingual surface of the teeth. The severity seems to correlate with the presence of reflux symptoms and the presence of an acidic milieu as the result of reflux in the proximal esophagus and oral cavity. The other common factors that can produce similar dental erosions are juice consumption and bulimia.

Eosinophilic Esophagitis and Non–Gastroesophageal Reflux Disease Esophagitis

Seema Khan and Susan R. Orenstein

EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis (EoE) is a chronic esophageal disorder characterized by infiltration of the esophageal epithelium by eosinophils, typically in a density exceeding 15 per high-power field. While infants and toddlers present commonly with vomiting, feeding problems, and poor weight gain, older children and adolescents usually experience solid food dysphagia with occasional food impactions or strictures and may complain of chest or epigastric pain. Most patients are male. The mean age at diagnosis is 7 yr (range: 1-17 yr), and the duration of symptoms is 3 yr. Many patients have other atopic diseases (or a positive family history) and associated food allergies; laboratory abnormalities can include peripheral eosinophilia and elevated immunoglobulin E (IgE) levels. The pathogenesis involves mainly T-helper type 2 cytokine-mediated pathways leading to production of a potent eosinophil chemoattractant, eotaxin-3, by esophageal epithelium. Endoscopically, the esophagus presents a granular, furrowed, ringed, or exudative appearance (Fig. 324-1); esophageal histology reveals eosinophilia, with cutpoints for diagnosis variably chosen at 15-20/high-power field. Up to 30% children with EoE have grossly normal esophageal mucosa. EoE is differentiated from gastroesophageal reflux disease by its general lack of erosive esophagitis, its greater eosinophil density, and its normal esophageal pH-multichannel intraluminal impedance results. A favorable response to proton pump inhibitor therapy should no longer be considered diagnostic of gastroesophageal reflux disease, as a subgroup of EoE patients with normal esophageal pH-multichannel intraluminal impedance also demonstrate histologic response, and constitute a proton pump inhibitor–responsive EoE group. This response may be because of an antieosinophil effect of the proton pump inhibitor class that is mediated by inhibition of eotaxin-3 secretion. Gastroesophageal reflux disease may be an important coexisting diagnosis. Evaluation of EoE should include a thorough search for food and environmental allergies via skin prick (IgE mediated) and patch (non–IgE mediated) tests.
followed by progressive retrosternal pain, odynophagia, and dysphagia. Endoscopy shows a focal lesion often localized to one of the anatomic narrowed regions of the esophagus or to an unsuspected pathologic narrowing. Treatment is supportive; lacking much evidence, antacids, topical anesthetics, and bland or liquid diets are often used.

**Bibliography is available at Expert Consult.**

**Treatment** involves dietary restrictions that take one of 3 forms: elimination diets guided by circumstantial evidence and food allergy test results; “6 food elimination diet” removing the major food allergens (milk, soy, wheat, egg, peanuts and tree nuts, seafood); and elemental diet composed exclusively of an amino acid–based formula. Successful clinical and histologic remission is observed in 70-98% patients. Topical and systemic corticosteroids have been used successfully for nonresponders and for nonallergic (“primary”) EoE, with symptomatic and histologic remission rates reaching 90%. Therapies under investigation include anti–interleukin-5 antibody (mepolizumab, reslizumab). Little is yet known about its natural history, but it seems that EoE is a chronic remitting and relapsing disorder with a potential for complications such as stricture formation.

**INFECTIVE ESOPHAGITIS**
Uncommon, and most often affecting immunocompromised children, infective esophagitis is caused by fungal agents, such as *Candida* and *Torulopsis glabrata*; viral agents, such as herpes simplex, cytomegalovirus, HIV, and varicella zoster; and, rarely, bacterial infections, including diphtheria and tuberculosis. The typical presenting signs and symptoms are odynophagia, dysphagia, and retrosternal pain; there may also be fever, nausea, and vomiting. Candida is the leading cause of infective esophagitis in immunocompetent and immunocompromised children, and presents with concurrent oropharyngeal infection in the majority of immunocompromised patients. Esophageal viral infections can also manifest in immunocompetent hosts as an acute febrile illness. Infectious esophagitis, like other forms of esophageal inflammation, occasionally progresses to esophageal stricture. Diagnosis of infectious esophagitis is made by endoscopy, usually notable for white plaques in candida, multiple superficial ulcers in herpes simplex virus, and single deep ulcer in cytomegalovirus, and histopathologic examination; adding polymerase chain reaction, tissue-viral culture, and immunocytochemistry enhances the diagnostic sensitivity and precision. Treatment is with appropriate antimicrobial agents, analgesics, and antacids.

**“PILL” ESOPHAGITIS**
This acute injury is produced by contact with a damaging agent. Medications implicated in “pill” esophagitis include tetracycline, potassium chloride, ferrous sulfate, nonsteroidal antiinflammatory medications, and alendronate. Most often the offending tablet is ingested at bedtime with inadequate water. This practice often produces acute discomfort

**Bibliography**

The majority of esophageal perforations in children are from blunt trauma (automobile injury, gunshot wounds, child abuse) or are iatrogenic. Cardiac massage, the Heimlich maneuver, nasogastric tube placement, traumatic laryngoscopy or endotracheal intubation, excessively vigorous postpartum suctioning of the airway during neonatal resuscitation, difficult upper endoscopy, sclerotherapy of esophageal varices, esophageal compression by a cuffed endotracheal tube, and dilation for therapy of achalasia and strictures have all been implicated. Esophageal rupture has followed forceful vomiting in patients with anorexia and has followed esophageal injury due to caustic ingestion, foreign body ingestion, food impactions, pill esophagitis, or eosinophilic esophagitis. Drinking cold, carbonated beverages rapidly is also known to cause esophageal perforation.

Spontaneous esophageal rupture (Boerhaave syndrome) is less common and is associated with sudden increases in intraesophageal pressure wrought by situations such as vomiting, coughing, or straining at stool. Children and adults with eosinophilic esophagitis have also been described with Boerhaave syndrome in the setting of forceful emesis in the aftermath of esophageal food impaction. In older children, as in adults, the tear occurs on the distal left lateral esophageal wall, because the smooth muscle layer here is weakest; in neonates (neonatal Boerhaave syndrome), spontaneous rupture is on the right.

Symptoms of esophageal perforation include pain, neck tenderness, dysphagia, subcutaneous crepitus, fever, and tachycardia; several patients with cervical perforations have displayed cold water polydipsia in an attempt to soothe pain in the throat. Perforations in the proximal thoracic esophagus tend to create signs (pneumomediastinum, effusions) in the left chest, whereas the signs of distal tears are more often on the right. Cervical spine and chest radiographs are often diagnostic, showing mediastinal widening or paracervical free air. If these x-rays are normal, an esophagogram using water-soluble contrast media should be performed, but esophagograms miss >30% of cervical perforations. Therefore, a negative water-soluble contrast esophagogram should be followed by a barium study; the greater density of barium can better demonstrate a small defect, though with a higher risk of inflammatory mediastinitis. Endoscopy may also be useful but carries a 30% false-negative rate. CT of the chest can assist in difficult cases.

Treatment must be individualized. Small tears in contained perforations with minimal mediastinal contamination in hemodynamically stable patients can be treated conservatively with broad-spectrum antibiotics, nothing given orally, gastric drainage, and parenteral nutrition. Chest exploration and direct surgical repair is infrequently indicated these days. Mortality rates range between 20% and 28%, with poor prognosis correlated with delayed diagnosis and interventions.

Bibliography is available at Expert Consult.
Bibliography
Esophageal varices form in adults with portal hypertension with hepatic venous pressure gradient above 10 mm Hg and pose a risk for bleeding at above 12 mm Hg (see Chapter 367). Spontaneous decompression of this hypertension through portosystemic collateral circulation via the coronary vein, in conjunction with the left gastric veins, gives rise to esophageal varices. Most esophageal varices are “uphill varices”; less commonly, those that arise in the absence of portal hypertension and with superior vena cava obstruction are “downhill varices.” Their treatment is directed at the underlying cause of the superior vena cava abnormality. Hemorrhage from esophageal varices is the major cause of morbidity and mortality from portal hypertension. Presentation is with significant hematemesis and melena; whereas most patients have liver disease, some children with entities such as extrahepatic portal venous thrombosis might have been previously asymptomatic. Any child with hematemesis and splenomegaly should be presumed to have esophageal variceal bleeding until proved otherwise.

Upper endoscopy is the preferred diagnostic test for esophageal varices, as it provides definitive diagnosis and delineation of details that aid in predicting the risk for bleeding, as well as enabling therapy for acute bleeding episodes via either sclerotherapy or band ligation. A report comprising a large series of children with biliary atresia and portal hypertension described endoscopic findings of large varices, red marks, and the presence of gastric varices as predictive of bleeding. Non-invasive methods of evaluating varices include barium contrast studies, ultrasound, computerized tomography, magnetic resonance, and elastography, but they are not recommended for routine diagnostic evaluation because of suboptimal accuracy compared to endoscopy.

Primary prophylaxis with the goal of preventing an initial hemorrhage can decrease the incidence of esophageal bleeding; the various modalities used are nonselective $\beta$ blockade (e.g., propranolol or nadolol), sclerotherapy, ligation, and portosystemic shunt surgery. Treated patients can bleed from congestive gastropathy, and no improvement in survival rate may be seen. Endoscopic variceal ligation in adults reduces the risk of first-time variceal bleeding when compared with untreated controls as well as patients treated with $\beta$ blockade; a decrease in mortality is only noted in comparison to the control group (see Chapter 367). The management of acute variceal bleeding must include attention to hemodynamic stability through blood transfusion, vasoactive drugs (e.g., octreotide), short-term antibiotic use, and endoscopy to perform ligation or sclerotherapy, as needed. Transjugular intrahepatic portosystemic shunt should be considered for variceal bleeding refractory to medical and endoscopic therapy. Secondary prophylaxis to reduce recurrence of bleeding uses nonselective $\beta$ blockade and obliteration of varices through serial treatment via ligation or sclerotherapy. The only randomized controlled pediatric study has shown superiority of ligation over sclerotherapy in reducing the risk for rebleeding and complications.

327 Foreign Bodies in the Esophagus
Seema Khan and Susan R. Orenstein

The majority (80%) of foreign-body ingestions occur in children, most of whom are between 6 mo and 3 yr of age. Older children and adolescents with developmental delays and those with psychiatric disorders are also at increased risk. The presentation of a foreign body lodged in the esophagus constitutes an emergency and is associated with significant morbidity and mortality because of the potential for perforation and sepsis. Coins and small toy items are the most commonly ingested foreign bodies. Food impactions are less common in children than in adults, and usually occur in children in association with eosinophilic esophagitis, repair of esophageal atresia, and Nissen fundoplication. Most esophageal foreign bodies lodge at the level of the cricopharyngeus (upper esophageal sphincter), the aortic arch, or just superior to the diaphragm at the gastroesophageal junction (lower esophageal sphincter).

At least 30% of children with esophageal foreign bodies may be totally asymptomatic, so any history of foreign body ingestion should be taken seriously and investigated. An initial bout of choking, gagging, and coughing may be followed by excessive salivation, dysphagia, food refusal, emesis, or pain in the neck, throat, or sternal notch regions. Respiratory symptoms such as stridor, wheezing, cyanosis, or dyspnea may be encountered if the esophageal foreign body impinges on the larynx or membranous posterior tracheal wall. Cervical swelling, erythema, or subcutaneous crepitations suggest perforation of the oropharynx or proximal esophagus.

Evaluation of the child with a history of foreign body ingestion starts with plain anteroposterior radiographs of the neck, chest, and abdomen, along with lateral views of the neck and chest. The flat surface of a coin in the esophagus is seen on the anteroposterior view and the edge on the lateral view (Fig. 327-1). The reverse is true for coins lodged in the trachea; here, the edge is seen anteroposteriorly and the flat side is seen
The Digestive System

In anticipation of passage into the stomach. If there are no problems in handling secretions, meat impactions can be observed for up to 12 hr. In patients without prior esophageal surgeries, glucagon (0.05 mg/kg IV) can sometimes be useful in facilitating passage of distal esophageal food boluses by decreasing the lower esophageal sphincter pressure. The use of meat tenderizers or gas-forming agents can lead to perforation and are not recommended. An alternative technique for removing esophageal coins impacted for <24 hr, performed most safely by experienced radiology personnel, consists of passage of a Foley catheter beyond the coin at fluoroscopy, inflating the balloon, and then pulling the catheter and coin back simultaneously with the patient in a prone oblique position. Concerns about the lack of direct mucosal visualization and, when tracheal intubation is not used, the lack of airway protection prompt caution in the use of this technique. Bougienage of esophageal coins toward the stomach in selected uncomplicated pediatric cases has been suggested to be an effective, safe, and economical modality where endoscopy might not be routinely available.

327.2 Caustic Ingestions

Seema Khan and Susan R. Orenstein

Ingestion of caustic substances is a world-wide public health problem accounting for a significant burden on healthcare resources. According to an inpatient database of U.S. pediatric hospital discharges in 2009, the estimated number of caustic ingestions was 807 (95% CI, 731-882) cases, amounting to $22,900,000 in total hospital charges. The medical sequelae of caustic ingestions are esophagitis, necrosis, perforation, and stricture formation (see Chapter 63). Most cases (70%) are accidental ingestions of liquid alkali substances that produce severe, deep liquefaction necrosis; drain decloggers are most common, and because they are tasteless, more is ingested (Table 327-1).

Acidic agents (20% of cases) are bitter, so less may be consumed; they produce coagulation necrosis and a somewhat protective thick eschar. They can produce severe gastritis, and volatile acids can result in respiratory symptoms. Children younger than 5 yr of age account for half of the cases of caustic ingestions, and boys are far more often involved than girls. Caustic ingestions produce signs and symptoms such as vomiting, drooling, refusal to drink, oral burns, dysphagia, dyspnea, abdominal pain, hematemesis, and stridor. Twenty percent of patients develop esophageal strictures. Absence of oropharyngeal lesions does not exclude the possibility of significant esophagogastric injury, which can

Bibliography
lead to perforation or stricture. The absence of symptoms is usually associated with no or minimal lesions; hematemesis, respiratory distress, or presence of at least 3 symptoms predicts severe lesions. An upper endoscopy is recommended as the most efficient means of rapid identification of tissue damage and must be undertaken in all symptomatic children.

Dilution by water or milk is recommended as acute treatment, but neutralization, induced emesis, and gastric lavage are contraindicated. Treatment depends on the severity and extent of damage (Table 327-2). Stricture risk is increased by circumferential ulcerations, white plaques, and sloughing of the mucosa. Strictures can require treatment with dilation, and in some severe cases, surgical resection and colon or small bowel interposition are needed. Silicone stents (self-expanding) placed endoscopically after a dilation procedure can be an alternative and conservative approach to the management of strictures. Rare late cases of superimposed esophageal carcinoma are reported. The role of corticosteroids is controversial; they are not recommended in 1st-degree burns, but they can reduce the risk of strictures in more-advanced

caustic esophagitis. Some centers also use antibiotics in the initial treatment of caustic esophagitis on the premise that reducing superinfection in the necrotic tissue bed will, in turn, lower the risk of stricture formation. However, multiple studies examining the role of antibiotics in caustic esophagitis have not reported a clinically significant benefit even in those with grade 2 or greater severity of esophagitis.

Stomach and Intestines

Section 4

Normal Development, Structure, and Function

Chris A. Liacouras

DEVELOPMENT

The primitive gut is recognizable by the 4th wk of gestation and is composed of the foregut, midgut, and hindgut. The foregut gives rise to the upper gastrointestinal tract, which includes the esophagus, stomach, and duodenum to the level of the insertion of the common bile duct. The midgut gives rise to the rest of the small bowel and the large bowel to the level of the midtransverse colon. The hindgut forms the remainder of the colon and upper anal canal. The rapid growth of the midgut causes it to protrude out of the abdominal cavity through the umbilical ring during fetal development. The midgut subsequently returns to the peritoneal cavity and rotates counterclockwise until the cecum lies in the right lower quadrant. The process is normally complete by the 8th wk of gestation.

The liver derives from the hepatic diverticulum that evolves into parenchymal cells, bile ducts, vascular structures, and hematopoietic and Kupffer cells. The extrahepatic bile ducts and gallbladder develop first as solid cords that canalize by the 3rd mo of gestation. The dorsal and ventral pancreatic buds grow from the foregut by the 4th wk of gestation. The 2 buds fuse by the 6th wk. Exocrine secretory capacity is present by the 5th mo.

Cis-regulatory genomic sequences govern gene expression during development. Modules of cis sequences are linked and allow a cascade of gene regulation that controls functional development. Extrinsic factors have the capacity to influence gene expression. In the gut, several growth factors, including growth factor-β, insulin-like growth factor, and growth factors found in human colostrum (human growth factor and epidermal growth factor), influence gene expression.

The small bowel is approximately 270 cm long at birth in a term neonate and grows to an adult length of 450-550 cm by 4 yr of age. The mucosa of the small intestine is composed of villi, which are finger-like projections of the mucosa into the bowel lumen that significantly expand the absorptive surface area. The mucosal surface is further expanded by a brush border containing digestive enzymes and transport mechanisms for mono-, di-, and oligosaccharides, amino acids, dipeptides and tripeptides, and fats. The villi originate in adjacent crypts and become functional as they migrate from the crypt up the villus. In young infants or malnourished children, the process may be delayed. Crypt cells also secrete fluid and electrolytes. In children of African and Asian ethnicity, lactase levels may begin to fall at 4 yr of age, leading to intolerance to mammalian milk. Mechanisms to digest and absorb protein, including pancreatic enzymes and mucosal mechanisms to transport amino acids, dipeptides, and tripeptides, are in place by the 20th wk of gestation.

Carbohydrates, protein, and fat are normally absorbed by the upper half of the small intestine; the distal segments represent a vast reserve of absorptive capacity. Most of the sodium, potassium, chloride, and water are absorbed in the small bowel. Bile salts and vitamin B₁₂ are selectively absorbed in the distal ileum, and iron is absorbed in the duodenum and proximal jejunum. Intraluminal digestion depends on the exocrine pancreas. Secretin and cholecystokinin stimulate synthesis and secretion of bicarbonate and digestive enzymes, which are released by the upper intestinal mucosa in response to various intraluminal stimuli, among them components of the diet.

Carbohydrate digestion is normally an efficient process that is completed in the distal duodenum. Starches are broken down to glucose, oligosaccharides, and disaccharides by pancreatic amylase. Residual glucose polymers are broken down at the mucosal level by glucoamylase. Lactose is broken down at the brush border by lactase, forming glucose and galactose; sucrose is broken down by sucrase-isomaltase to fructose and glucose. Galactose and glucose are primarily transported into the cell by a sodium- and energy-dependent process, whereas fructose is transported by facilitated diffusion.

Proteins are hydrolyzed by pancreatic enzymes, including trypsin, chymotrypsin, elastase, and carboxypeptidases, into individual amino acids and dipeptides and oligopeptides. The pancreatic enzymes are secreted as proenzymes, which are activated by release of the mucosal enzyme entero-kinase. Oligopeptides are further broken down by the brush border by peptidases into dipeptides, tripeptides, and amino acids. Protein can enter the cell by separate noncompetitive carriers that can transport individual amino acids or dipeptides and tripeptides similar to those in the renal tubule. The human gut is capable of absorbing antigenic...
intact proteins in the 1st few wk of life because of “leaky” junctions between enterocytes. Entry of potential protein antigens through the mucosal barrier might have a role in later food- and microbe-induced symptoms.

**Fat absorption** occurs in 2 phases. Dietary triglycerides are broken down into monoglycerides and free fatty acids by pancreatic lipase and colipase. The free fatty acids are subsequently emulsified by bile acids, forming micelles with phospholipids and other fat-soluble substances, and are transported to the cell membrane, where they are absorbed. The fats are re-esterified in the enterocyte, forming chylomicrons that are transported through the intestinal lymphatics to the thoracic duct. Medium-chain fats are absorbed more efficiently and can directly enter the cell. They are subsequently transported to the liver via the portal system. Fat absorption can be affected at any stage of the digestion and absorption process. Decreased pancreatic enzymes occur in cystic fibrosis, cholestatic liver disease leads to poor bile salt production and micelle formation, celiac disease affects mucosal surface area, abnormal chylomicron formation occurs in abetalipoproteinemia, and intestinal lymphangiectasia affects transport of the chylomicrons.

Fat absorption is less efficient in the neonate compared with adults. Premature infants can lose up to 20% of their fat calories compared with up to 6% in the adult. Decreased synthesis of bile acids and pancreatic lipase and decreased efficiency of ileal absorption are contributing factors. Fat digestion in the neonate is facilitated by lingual and gastric lipases. Bile salt–stimulated lipase in human milk augments the action of pancreatic lipase. Infants with malabsorption of fat are usually fed with formulas that have a greater percentage of medium-chain triglycerides, which are absorbed independently of bile salts.

The colon is a 75-100 cm sacculated tube formed by 3 strips of longitudinal muscle called *taenia coli* that traverse its length and fold the mucosa into haustra. Haustra and taenia appear by the 12th wk of gestation. The most common motor activity in the colon is nonpropulsive rhythmic segmentation that acts to mix the chyme and expose the contents to the colonic mucosa. Mass movement within the colon typically occurs after a meal. The colon extracts additional water and electrolytes from the luminal contents to render the stools partially or completely solid. The colon also acts to scavenge by-products of bacterial degradation of carbohydrates. Stool is stored in the rectum until distention triggers a defecation reflex that, when assisted by voluntary relaxation of the external sphincter, permits evacuation.
Chapter 329 • Pyloric Stenosis and Other Congenital Anomalies of the Stomach

329.1 Hypertrophic Pyloric Stenosis
Anna K. Hunter and Chris A. Liacouras

Hypertrophic pyloric stenosis occurs in 1-3 per 1,000 infants in the United States. It is more common in whites of northern European ancestry, less common in blacks, and rare in Asians. Males (especially firstborns) are affected approximately 4-6 times as often as females. The offspring of a mother and, to a lesser extent, the father who had pyloric stenosis are at higher risk for pyloric stenosis. Pyloric stenosis develops in approximately 20% of the male and 10% of the female descendants of a mother who had pyloric stenosis. The incidence of pyloric stenosis is increased in infants with B and O blood groups. Pyloric stenosis is occasionally associated with other congenital defects, including tracheoesophageal fistula and hypoplasia or agenesis of the inferior labial frenulum.

ETIOLOGY

The cause of pyloric stenosis is unknown, but many factors have been implicated. Pyloric stenosis is usually not present at birth and is more concordant in monozygotic than dizygotic twins. It is unusual in stillbirths and probably develops after birth. Pyloric stenosis has been associated with eosinophilic gastroenteritis, Apert syndrome, Zellweger syndrome, trisomy 18, Smith-Lemli-Opitz syndrome, and Cornelia de Lange syndrome. An association has been found with the use of erythromycin in neonates with highest risk if the medication is given within the 1st 2 wk of life. There have also been reports of higher incidence of pyloric stenosis among mostly female infants of mothers treated with macrolide antibiotics during pregnancy and breastfeeding. Abnormal muscle innervation, elevated serum levels of prostaglandins, and infant hypergastrinemia has been implicated. Reduced levels of neuronal nitric oxide synthase have been found with altered expression of the neuronal nitric oxide synthase exon 1c regulatory region, which influences the expression of the neuronal nitric oxide synthase gene. Reduced nitric oxide might contribute to the pathogenesis of pyloric stenosis.

CLINICAL MANIFESTATIONS

Nonbilious vomiting is the initial symptom of pyloric stenosis. The vomiting may or may not be projectile initially but is usually progressive, occurring immediately after a feeding. Emesis might follow each feeding, or it may be intermittent. The vomiting usually starts after 3 wk of age, but symptoms can develop as early as the 1st wk of life and as late as the 5th mo. Approximately 20% have intermittent emesis from birth that then progresses to the classic picture. After vomiting, the infant is hungry and wants to feed again. As vomiting continues, a progressive loss of fluid, hydrogen ion, and chloride leads to hypochloremic metabolic alkalosis. Greater awareness of pyloric stenosis has led to earlier identification of patients with fewer instances of chronic malnutrition and severe dehydration and at times a subclinical self-resolving hypertrophy.

Hyperbilirubinemia is the most common clinical association of pyloric stenosis, also known as icteropyloric syndrome. Unconjugated hyperbilirubinemia is more common than conjugated and usually resolves with surgical correction. It may be associated with a decreased level of glucuronyl transferase as seen in approximately 5% of affected infants; mutations in the bilirubin uridine diphosphate glucuronosyltransferase gene (UGT1A1) have also been implicated. If conjugated hyperbilirubinemia is a part of the presentation, other etiologies need to be investigated. Other coexistent clinical diagnoses have been described, including eosinophilic gastroenteritis, hiatal hernia, peptic ulcer, congenital nephrotic syndrome, congenital heart disease, and congenital hypothyroidism.

The diagnosis has traditionally been established by palpating the pyloric mass. The mass is firm, movable, approximately 2 cm in length, olive shaped, hard, best palpated from the left side, and located above and to the right of the umbilicus in the midepigastrium beneath the liver’s edge. The olive is easiest palpated after an episode of vomiting. After feeding, there may be a visible gastric peristaltic wave that progresses across the abdomen (Fig. 329-1).

Two imaging studies are commonly used to establish the diagnosis. Ultrasound examination confirms the diagnosis in the majority of cases. Criteria for diagnosis include pyloric thickness 3-4 mm, an overall pyloric length 15-19 mm, and pyloric diameter of 10-14 mm (Fig. 329-2). Ultrasonography has a sensitivity of approximately 95%. When contrast studies are performed, they demonstrate an elongated pyloric channel (string sign), a bulge of the pyloric muscle into the antrum (shoulder sign), and parallel streaks of barium seen in the narrowed channel, producing a “double tract sign” (Fig. 329-3).
The preoperative treatment is directed toward correcting the fluid, acid–base, and electrolyte losses. Correction of the alkalosis is essential to prevent postoperative apnea, which may be associated with anesthesia. Most infants can be successfully rehydrated within 24 hr. Vomiting usually stops when the stomach is empty, and only an occasional infant requires nasogastric suction.

The surgical procedure of choice is pyloromyotomy. The traditional Ramstedt procedure is performed through a short transverse skin incision. The underlying pyloric mass is cut longitudinally to the layer of the submucosa, and the incision is closed. Laparoscopic technique is equally successful and in one study resulted in a shorter time to full feedings and discharge from the hospital as well as greater parental satisfaction. The success of laparoscopy depends on the skill of the

**DIFFERENTIAL DIAGNOSIS**

Gastric waves are occasionally visible in small, emaciated infants who do not have pyloric stenosis. Infrequently, gastroesophageal reflux, with or without a hiatal hernia, may be confused with pyloric stenosis. Gastroesophageal reflux disease can be differentiated from pyloric stenosis by radiographic studies. Adrenal insufficiency from the adrenogenital syndrome can simulate pyloric stenosis, but the absence of a metabolic acidosis and elevated serum potassium and urinary sodium concentrations of adrenal insufficiency aid in differentiation (see Chapter 576). Inborn errors of metabolism can produce recurrent emesis with alkalosis (urea cycle) or acidosis (organic acidemia) and lethargy, coma, or seizures. Vomiting with diarrhea suggests gastroenteritis, but patients with pyloric stenosis occasionally have diarrhea. Rarely, a pyloric membrane or pyloric duplication results in projectile vomiting, visible peristalsis, and, in the case of a duplication, a palpable mass. Duodenal stenosis proximal to the ampulla of Vater results in the clinical features of pyloric stenosis but can be differentiated by the presence of a pyloric mass on physical examination or ultrasonography.

**TREATMENT**

The preoperative treatment is directed toward correcting the fluid, acid–base, and electrolyte losses. Correction of the alkalosis is essential to prevent postoperative apnea, which may be associated with anesthesia. Most infants can be successfully rehydrated within 24 hr. Vomiting usually stops when the stomach is empty, and only an occasional infant requires nasogastric suction.

The surgical procedure of choice is pyloromyotomy. The traditional Ramstedt procedure is performed through a short transverse skin incision. The underlying pyloric mass is cut longitudinally to the layer of the submucosa, and the incision is closed. Laparoscopic technique is equally successful and in one study resulted in a shorter time to full feedings and discharge from the hospital as well as greater parental satisfaction. The success of laparoscopy depends on the skill of the
surgeon. Postoperative vomiting occurs in half the infants and is thought to be secondary to edema of the pylorus at the incision site. In most infants, however, feedings can be initiated within 12-24 hr after surgery and advanced to maintenance oral feedings within 36-48 hr after surgery. Persistent vomiting suggests an incomplete pyloromyotomy, gastritis, gastroesophageal reflux disease, or another cause of the obstruction. The surgical treatment of pyloric stenosis is curative, with an operative mortality of 0-0.3%. Endoscopic balloon dilation has been successful in infants with persistent vomiting secondary to incomplete pyloromyotomy.

Conservative management with nasoduodenal feedings is advisable in patients who are not good surgical candidates. Oral and intravenous atropine sulfate (pyloric muscle relaxant) has also been described when surgical treatment is not available with 80% success rate described in some studies. In conservative protocols atropine is administered intravenously at a dose of 0.01 mg/kg 6 times a day 5 min before feeding. During atropine infusion, the heart rate needs to be continuously monitored by electrocardiography. Oral feeding is started at a volume of 10 mL formula, 6 times a day. The volume is increased day by day until patients tolerate 150 mL/kg/day unless vomiting occurs more than twice a day. When patients are able to tolerate the full volume of formula without vomiting more than twice a day, 0.02 mg/kg atropine is administered orally 6 times a day before feeding. As the conservative management takes longer and oral feedings may not be tolerated at first, worsening of the nutrition status may occur and total parenteral nutrition may be required. It was also postulated that surgical management is more time and cost effective.

### 329.2 Congenital Gastric Outlet Obstruction

**Anna K. Hunter and Chris A. Liacouras**

Gastric outlet obstruction resulting from pyloric atresia and antral webs is uncommon and accounts for <1% of all the atresias and diaphragms of the alimentary tract. The cause of the defects is unknown. Pyloric atresia has been associated with epidermolysis bullosa and usually presents in early infancy. The gender distribution is equal.

**CLINICAL MANIFESTATIONS**

Infants with pyloric atresia present with nonbilious vomiting, feeding difficulties, and abdominal distention during the 1st day of life. Polyhydramnios occurs in the majority of cases, and low birth weight is common. The gastric aspirate at birth is large (>20 mL fluid) and should be removed to prevent aspiration. Rupture of the stomach may occur as early as the 1st 12 hr of life. Infants with antral web may present with less dramatic symptoms, depending on the degree of obstruction. Older children with antral webs present with nausea, vomiting, abdominal pain, and weight loss.

**DIAGNOSIS**

The diagnosis of congenital gastric outlet obstruction is suggested by the finding of a large, dilated stomach on abdominal plain radiographs or in utero ultrasonography. Upper gastrointestinal (GI) contrast series is usually diagnostic and demonstrates a pyloric dimple. When contrast studies are performed, care must be taken to avoid possible aspiration. An antral web may appear as a thin septum near the pyloric channel. In older children, endoscopy has been helpful in identifying antral webs.

**TREATMENT**

The treatment of all causes of gastric outlet obstruction in neonates starts with the correction of dehydration and hypochloremic alkalosis. Persistent vomiting should be relieved with nasogastric decompression. Surgical or endoscopic repair should be undertaken when a patient is stable.

### 329.3 Gastric Duplication

**Anna K. Hunter and Chris A. Liacouras**

Gastric duplications are uncommon cystic or tubular structures that usually occur within the wall of the stomach. They account for 2-7% of all GI duplications. They are most commonly located on the greater curvature. Most are <12 cm in diameter and do not usually communicate with the stomach lumen; however, they do have common blood supply. Associated anomalies occur in as many as 35% of patients. Several hypotheses for the etiology of the duplication cysts have been developed including the splitting notochord theory, diverticulation, canalization defects, and caudal twinning.

The most common clinical manifestations are associated with partial or complete gastric outlet obstruction. In 33% of patients, the cyst may be palpable. Communicating duplications can cause gastric ulceration and be associated with hematemesis or melena.

Radiographic studies usually show a paragastric mass displacing stomach. Ultrasound can show the inner hyperechoic mucosal and outer hypoechoic muscle layers that are typical of GI duplications. Surgical excision is the treatment for symptomatic gastric duplications.

Bibliography is available at Expert Consult.

### 329.4 Gastric Volvulus

**Anna K. Hunter and Chris A. Liacouras**

The stomach is tethered longitudinally by the gastrophepatic, gastro-splenic, and gastrocolic ligaments. In the transverse axis, it is tethered by the gastrophrenic ligament and the retroperitoneal attachment of the duodenum. A volvulus occurs when one of these attachments is absent or elongated, allowing the stomach to rotate around itself. In some children, other associated defects are present, including intestinal malrotation, diaphragmatic defects, hiatal hernia, or adjacent organ abnormalities such as asplenia. Volvulus can occur along the longitudinal axis, producing organoaxial volvulus, or along the transverse axis, producing mesenteroaxial volvulus. Combined volvulus occurs if the stomach rotates around both organoaxial and mesentero-axial axes.

The clinical presentation of gastric volvulus is nonspecific and suggests high intestinal obstruction. Gastric volvulus in infancy is usually associated with nonbilious vomiting and epigastric distention. It has also been associated with episodes of dyspnea and apnea in this age group. Acute volvulus can advance rapidly to strangulation and perforation. Chronic gastric volvulus is more common in older children; the children present with a history of emesis, abdominal pain and distention, early satiety, and failure to thrive.

The diagnosis is suggested in plain abdominal radiographs by the presence of a dilated stomach. Erect abdominal films demonstrate a double fluid level with a characteristic “beak” near the lower esophageal junction in mesenteroaxial volvulus. The stomach tends to lie in a vertical plane. In organoaxial volvulus, a single air–fluid level is seen without the characteristic beak with stomach lying in a horizontal plane. Upper GI series has also been used to aid the diagnosis.

**Treatment** of acute gastric volvulus is emergent surgery once a patient is stabilized. Laparoscopic gastroscopy is the most common surgical approach. In selected cases of chronic volvulus in older patients, endoscopic correction has been successful.

### 329.5 Hypertrophic Gastropathy

**Anna K. Hunter and Chris A. Liacouras**

Hypertrophic gastropathy in children is uncommon and, in contrast to that in adults (Ménétrier disease), is usually a transient, benign, and self-limited condition.
Bibliography
Bibliography
Bibliography
PATHOGENESIS
The condition is most often secondary to cytomegalovirus (CMV) infection, but other agents, including herpes simplex virus, *Giardia*, and *Helicobacter pylori*, are also implicated. The pathophysiologic mechanisms underlying the clinical picture are not completely understood but might involve widening of gap junctions between gastric epithelial cells with resultant fluid and protein losses. There is an association with increased expression of transforming growth factor-α in gastric mucosal tissue shown in CMV induced gastropathy. *H. pylori* infection can cause the elevation of serum glucagon-like peptide-2 levels, a mucosal growth-inducing gut hormone.

CLINICAL MANIFESTATIONS
Clinical manifestations include vomiting, anorexia, upper abdominal pain, diarrhea, edema (hypoproteinemic protein-losing enteropathy), ascites, and, rarely, hematemesis if ulceration occurs.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
The mean age at diagnosis is 5 yr (range: 2 days-17 yr); the illness usually lasts 2-14 wk, with complete resolution being the rule. Endoscopy with biopsy and tissue CMV polymerase chain reaction is diagnostic. Endoscopy shows characteristic enlarged gastric folds. The upper GI series might show thickened gastric folds. The differential diagnosis includes eosinophilic gastroenteritis, gastric lymphoma or carcinoma, Crohn disease, and inflammatory pseudotumor.

TREATMENT
Therapy is supportive and should include adequate hydration, antisecretory agents (*H₂* receptor blockade, acid suppression with proton pump inhibitors), and albumin replacement if the hypoalbuminemia is symptomatic. When *H. pylori* are detected, appropriate treatment is recommended. Ganciclovir in CMV-positive gastropathy is indicated only in severe cases. There are no official guidelines as far as the length of treatment. In practice, IV therapy is initiated for the 1st 24-48 hr. Treatment in continued with oral valganciclovir for a total of 3 wk.

Complete recovery is the rule. Hypertrophic gastropathy should be considered in a previously healthy child with new onset edema and no other causes of protein losses. This is not a chronic condition in children. Disease tends to have much more severe course in adult patients.

Bibliography is available at Expert Consult.
Bibliography
Intestinal obstruction can be further classified as either intrinsic or extrinsic based on underlying etiology. Intrinsic causes include inherent abnormalities of intestinal innervation, mucus production, or tubular anatomy. Among these, congenital disruption of the tubular structure is most common and can manifest as obliteration (atresia) or narrowing (stenosis) of the intestinal lumen. More than 90% of intestinal stenosis and atresia occurs in the duodenum, jejunum, and ileum. Rare cases occur in the colon, and these may be associated with more proximal atresias.

Extrinsic causes of congenital intestinal obstruction involve compression of the bowel by vessels (e.g., preduodenal portal vein), organs (e.g., annular pancreas), and cysts (e.g., duplication, mesenteric). Abnormalities in intestinal rotation during fetal development also represent a unique extrinsic cause of congenital intestinal obstruction. Malrotation is associated with inadequate mesenteric attachment of the intestine to the posterior abdominal wall, which leaves the bowel vulnerable to autoobstruction as a result of intestinal twisting or volvulus. Malrotation is commonly accompanied by congenital adhesions that can compress and obstruct the duodenum as they extend from the cecum to the right upper quadrant.

Obstruction is typically associated with bowel distention, which is caused by an accumulation of ingested food, gas, and intestinal secretions proximal to the point of obstruction. As the bowel dilates, absorption of intestinal fluid is decreased and secretion of fluid and electrolytes is increased. This shift results in isotonic intravascular depletion, which is usually associated with hypokalemia. Bowel distention also results in a decrease in blood flow to the obstructed bowel. As blood flow is shifted away from the intestinal mucosa, there is loss of mucosal integrity. Bacteria proliferate in the stagnant bowel, with a predominance of coliforms and anaerobes. This rapid proliferation of bacteria, coupled with the loss of mucosal integrity, allows bacterial to translocate across the bowel wall and potentially lead to endotoxemia, bacteremia, and sepsis.

The clinical presentation of intestinal obstruction varies with the cause, level of obstruction, and time between the obstructing event and the patient’s evaluation. Classic symptoms of obstruction in the neonate include vomiting, abdominal distention, and obstipation. Obstruction high in the intestinal tract results in large-volume, frequent, bilious emesis with little or no abdominal distention. Pain is intermittent and is usually relieved by vomiting. Obstruction in the distal small bowel leads to moderate or marked abdominal distention with emesis that is progressively feculent. Both proximal and distal obstructions are eventually associated with obstruction. However, meconium stools can be passed initially if the obstruction is in the upper part of the intestinal tract or if the obstruction developed late in intrauterine life.

The diagnosis of congenital bowel obstruction relies on a combination of history, physical examination, and radiologic findings. In certain cases, the diagnosis is suggested in the prenatal period. Routine prenatal ultrasound can detect polyhydramnios, which often accompanies high intestinal obstruction. The presence of polyhydramnios should prompt aspiration of the infant's stomach immediately after birth. Aspiration of more than 15-20 mL of fluid, particularly if it is bile stained, is highly indicative of proximal intestinal obstruction.

In the postnatal period, a plain radiograph is the initial diagnostic study and can provide valuable information about potential associated complications. With completely obstructing lesions, plain radiographs reveal bowel distention proximal to the point of obstruction. Upright or crosstable lateral views typically demonstrate a series of air–fluid levels in the distended loops. Caution must be exercised in using plain films to determine the location of intestinal obstruction. Because colonic haustra are not fully developed in the neonate, small and large bowel obstructions may be difficult to distinguish with plain films. In these cases, contrast studies of the bowel or computed tomography images may be indicated. Oral or nasogastric contrast medium may be used to identify obstructing lesions in the proximal bowel, and contrast enemas may be used to diagnose more-distal entities. Indeed, enemas may also play a therapeutic role in relieving distal obstruction caused by meconium ileus or meconium plug syndrome.

Initial treatment of infants and children with bowel obstruction must be directed at fluid resuscitation and stabilizing the patient. Nasogastric decompression usually relieves pain and vomiting. After appropriate cultures, broad-spectrum antibiotics are usually started in ill-appearing neonates with bowel obstruction and those with suspected strangulating infarction. Patients with strangulation must have...
immediate surgical relief before the bowel infarcts, resulting in gangrene and intestinal perforation. Extensive intestinal necrosis results in short bowel syndrome (see Chapter 330.7). Nonoperative conservative management is usually limited to children with suspected adhesions or inflammatory strictures that might resolve with nasogastric decompression or anti-inflammatory medications. If clinical signs of improvement are not evident within 12-24 hr, then operative intervention is usually indicated.

**330.1 Duodenal Obstruction**

*Christina Bales and Chris A. Liacouras*

Congenital duodenal obstruction occurs in 2.5-10 per 100,000 live births. In most cases, it is caused by atresia, an intrinsic defect of bowel formation. It can also result from extrinsic compression by abnormal neighboring structures (e.g., annular pancreas, preduodenal portal vein), duplication cysts, or congenital bands associated with malrotation. Although intrinsic and extrinsic causes of duodenal obstruction occur independently, they can also coexist. Thus, a high index of suspicion for more than one underlying etiology may be critical to avoiding unnecessary reoperations in these infants.

Duodenal atresia complicates 1 per 10,000 live births and accounts for 25–40% of all intestinal atresias. In contrast to more-distal atresias, which likely arise from prenatal vascular accidents, duodenal atresia results from failed recanalization of the intestinal lumen during gestation. Throughout the 4th and 5th wk of normal fetal development, the duodenal mucosa exhibits rapid proliferation of epithelial cells. Persistence of these cells, which should degenerate after the 7th wk of gestation, leads to occlusion of the lumen (atresia) in approximately two-thirds of cases and narrowing (stenosis) in the remaining one-third. Duodenal atresia can take several forms, including a thin membrane that occludes the lumen, a short fibrous cord that connects 2 blind duodenal pouches, or a gap that spans 2 nonconnecting ends of the duodenum. The membranous form is most common, and it almost invariably occurs near the ampulla of Vater. In rare cases, the membrane is distensible and is referred to as a windsock web. This unusual form of duodenal atresia causes obstruction several centimeters distal to the origin of the membrane.

Approximately 50% of infants with duodenal atresia are premature. Concomitant congenital anomalies are common and include congenital heart disease (30%), malrotation (20–30%), annular pancreas (30%), renal anomalies (5–15%), esophageal atresia with or without tracheoesophageal fistula (5–10%), skeletal malformations (5%), and anorectal anomalies (5%). Of these anomalies, only complex congenital heart disease is associated with increased mortality. Annular pancreas is associated with increased late complications, including gastroesophageal reflux disease, peptic ulcer disease, pancreatitis, gastric outlet and recurrent duodenal obstruction, and gastric cancer. Thus, long-term follow-up of these patients into adulthood is warranted. Nearly half of patients with duodenal atresia have chromosome abnormalities; trisomy 21 is identified in up to one-third of patients.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

The hallmark of duodenal obstruction is bilious vomiting without abdominal distention, which is usually noted on the 1st day of life. Peristaltic waves may be visualized early in the disease process. A history of polyhydramnios is present in half the pregnancies and is caused by inadequate absorption of amniotic fluid in the distal intestine. This fluid may be bile-stained because of intrauterine vomiting. Jaundice is present in one-third of the infants.

The diagnosis is suggested by the presence of a “double-bubble” sign on a plain abdominal radiograph (Fig. 330-1). The appearance is caused by a distended and gas-filled stomach and proximal duodenum, which are invariably connected. Contrast studies are occasionally needed to exclude malrotation and volvulus because intestinal infarction can occur within 6–12 hr if the volvulus is not relieved. Contrast studies are generally not necessary and may be associated with aspiration. Prenatal diagnosis of duodenal atresia is readily made by fetal ultrasonography, which reveals a sonographic double-bubble. Prenatal identification of duodenal atresia is associated with decreased morbidity and fewer hospitalization days.

**TREATMENT**

The initial treatment of infants with duodenal atresia includes nasogastric or orogastric decompression and intravenous fluid replacement. Echocardiography, renal ultrasound, and radiology of the chest and spine should be performed to evaluate for associated anomalies. Definitive correction of the atresia is usually postponed until life-threatening anomalies are evaluated and treated.

The typical surgical repair for duodenal atresia is duodenoduodenostomy. This procedure is also preferred in cases of concomitant or isolated annular pancreas. In these instances, the duodenoduodenostomy is performed without dividing the pancreas. The dilated proximal bowel might have to be tapered to improve peristalsis. Postoperatively, a gastrostomy tube can be placed to drain the stomach and protect the airway. Intravenous nutritional support or a transanastomotic jejunal tube is needed until an infant starts to feed orally. Long-term prognosis is excellent, approaching 90% survival in most series.

**330.2 Jejunal and Ileal Atresia and Obstruction**

*Christina Bales and Chris A. Liacouras*

The primary etiologies of congenital small bowel obstruction involve intrinsic abnormalities in anatomic development (jejunoileal stenosis
Bibliography

**Chapter 330 • Intestinal Atresia, Stenosis, and Malrotation**

**Bibliography**

and atresia), mucus secretion (meconium ileus), and bowel wall inervation (long-segment Hirschsprung disease).

Jejunoileal atresias are generally attributed to intraterine vascular accidents, which result in segmental infarction and resorption of the fetal intestine. Underlying events that potentiate vascular compromise include intestinal volvulus, intussusception, meconium ileus, and strangulating herniation through an abdominal wall defect associated with gastroschisis or omphalocle. Maternal behaviors that promote vasoconstriction, such as cigarette smoking and cocaine use, might also have a role. Only a few cases of familial inheritance have been reported. In these families, multiple intestinal atresias have occurred in an autosomal recessive pattern. Jejunoileal atresias have been linked with multiple births, low birthweight, and prematurity. Unlike atresia in the duodenum, they are not commonly associated with extraintestinal anomalies.

Five types of jejunal and ileal atresias are encountered (Fig. 330-2). In type I, a mucosal web occludes the lumen but continuity is maintained between the proximal and distal bowel. Type II involves a small-diameter solid cord that connects the proximal and distal bowel. Type III is divided into 2 subtypes. Type IIIa occurs when both ends of the bowel end in blind loops, accompanied by a small mesenteric defect. Type IIIb is similar, but it is associated with an extensive mesenteric defect and a loss of the normal blood supply to the distal bowel. The distal ileum coils around the ileocolic artery, from which it derives its entire blood supply, producing an "apple-peel" appearance. This anomaly is associated with prematurity, an unusually short distal ileum, and significant foreshortening of the bowel. Type IV involves multiple atresias. Types II and III are the most common, each accounting for 30-35% of cases. Types IIIb and IV account for the remaining 10-20% of cases, with IIIb being the least-common configuration.

Meconium ileus occurs primarily in newborn infants with cystic fibrosis, an exocrine gland defect of chloride transport that results in abnormally viscous secretions. Approximately 80-90% of infants with meconium ileus have cystic fibrosis, but only 10-15% of infants with cystic fibrosis present with meconium ileus. In simple cases, the distal 20-30 cm of ileum is collapsed and filled with pellets of pale stool. The proximal bowel is dilated and filled with thick meconium that resembles sticky syrup or glue. Peristalsis fails to propel this viscid material forward, and it becomes impacted in the ileum. In complicated cases, a volvulus of the dilated proximal bowel can occur, resulting in intestinal ischemia, atresia, and/or perforation. Perforation in utero results in meconium peritonitis, which can lead to potentially obstructing adhesions and calcifications.

Both intestinal atresia and meconium ileus must be distinguished from long-segment Hirschsprung disease. This condition involves congenital absence of ganglion cells in the myenteric and submucosal plexuses of the bowel wall. In a small subset (5%) of patients, the aganglionic segment includes the terminal ileum in addition to the entire length of the colon. Infants with long-segment Hirschsprung disease present with a dilated small intestine that is gangionated but has hypertrophied walls, a funnel-shaped transitional hypoganglionic zone, and a collapsed distal aganglionic bowel.

CLINICAL MANIFESTATION AND DIAGNOSIS

Distal intestinal obstruction is less likely than proximal obstruction to be detected in utero. Polyhydramnios is identified in 20-35% of jejunoileal atresias, and it may be the first sign of intestinal obstruction. Abdominal distention is rarely present at birth, but it develops rapidly after initiation of feeds in the 1st 12-24 hr. Distention is often accompanied by vomiting, which is often bilious. Up to 80% of infants fail to pass meconium in the 1st 24 hr of life. Jaundice, associated with unconjugated hyperbilirubinemia, is reported in 20-30% of patients.

In patients with obstruction caused by jejunouileal atresia or long-segment Hirschsprung disease, plain radiographs typically demonstrate multiple air-fluid levels proximal to the obstruction in the upright or lateral decubitus positions (Fig. 330-3). These levels may be absent in patients with meconium ileus because the viscosity of the secretions in the proximal bowel prevents layering. Instead, a typical hazy or ground-glass appearance may be appreciated in the right lower quadrant. This haziness is caused by small bubbles of gas that become trapped in inspissated meconium in the terminal ileal region. If there is meconium peritonitis, patchy calcification may also be noted, particularly in the flanks. Plain films can reveal evidence of pneumatoneumatus due to intestinal perforation. Air may be seen in the subphrenic regions on the upright view and over the liver in the left lateral decubitus position.

Because plain radiographs do not reliably distinguish between small and large bowel in neonates, contrast studies are often required to localize the obstruction. Water-soluble enemas (Gastrografin, Hypaque) are particularly useful in differentiating atresia from meconium ileus and Hirschsprung disease. A small "microcolon" suggests distuse and the presence of obstruction proximal to the ileocecal valve. Abdominal ultrasound may be an important adjunctive study, which
can distinguish meconium ileus from ileal atresia and also identify concomitant intestinal malrotation.

**TREATMENT**

Patients with small bowel obstruction should be stable and in adequate fluid and electrolyte balance before operation or radiographic attempts at disimpaction unless volvulus is suspected. Documented infections should be treated with appropriate antibiotics. Prophylactic antibiotics are usually given before surgery.

Ileal or jejunal atresia requires resection of the dilated proximal portion of the bowel followed by end-to-end anastomosis. If a simple mucosal diaphragm is present, jejunoplasty or ileoplasty with partial excision of the web is an acceptable alternative to resection. In uncomplicated meconium ileus, Gastrografin enemas diagnose the obstruction and wash out the inspissated material. Gastrografin is hypertonic, and care must be taken to avoid dehydration, shock, and bowel perforation. The enema may have to be repeated after 8-12 hr. Resection after reduction is not needed if there have been no ischemic complications.

Approximately 50% of patients with simple meconium ileus do not adequately respond to water-soluble enemas and need laparotomy. Operative management is indicated when the obstruction cannot be relieved by repeated attempts at nonoperative management and for infants with complicated meconium ileus. The extent of surgical intervention depends on the degree of pathology. In simple meconium ileus, the plug can be relieved by manipulation or direct enteral irrigation with N-acetylcysteine following an enterotomy. In complicated cases, bowel resection, peritoneal lavage, abdominal drainage, and stoma formation may be necessary. Total parenteral nutrition is generally required.

**Bibliography is available at Expert Consult.**

### 330.3 Malrotation

*Melissa Kennedy and Chris A. Liacouras*

Malrotation is incomplete rotation of the intestine during fetal development and involves the intestinal nonrotation or incomplete rotation around the superior mesenteric artery. The gut starts as a straight tube from stomach to rectum. Intestinal rotation and attachment begins in the 5th wk of gestation when the midgut (distal duodenum to midtransverse colon) begins to elongate and progressively protrudes into the umbilical cord until it lies totally outside the confines of the abdominal cavity. As the developing bowel rotates in and out of the abdominal cavity, the superior mesenteric artery, which supplies blood to this section of gut, acts as an axis. The duodenum, on reentering the abdominal cavity, moves to the region of the ligament of Treitz, and the colon that follows is directed to the left lower quadrant. The cecum subsequently rotates counterclockwise within the abdominal cavity and comes to lie in the right lower quadrant. The duodenum becomes fixed to the posterior abdominal wall before the colon is completely rotated. After rotation, the right and left colon and the mesenteric root become fixed to the posterior abdomen. These attachments provide a broad base of support to the mesentery and the superior mesenteric artery, thus preventing twisting of the mesenteric root and kinking of the vascular supply. Abdominal rotation and attachment are completed by the 12th wk of gestation.

Nonrotation occurs when the bowel fails to rotate after it returns to the abdominal cavity. The 1st and 2nd portions of the duodenum are in their normal position, but the remainder of the duodenum, jejunum, and ileum occupy the right side of the abdomen and the colon is located on the left. The most common type of malrotation involves failure of the cecum to move into the right lower quadrant (Fig. 330-4). The usual location of the cecum is in the subhepatic area. Failure of the cecum to rotate properly is associated with failure to form the normal broad-based adherence to the posterior abdominal wall. The mesentery, including the superior mesenteric artery, is tethered by a narrow stalk, which can twist around itself and produce a midgut volvulus. Bands of tissue (Ladd bands) can extend from the cecum to the right upper quadrant, crossing, and possibly obstructing, the duodenum.

Malrotation and nonrotation are often associated with other anomalies of the abdominal wall such as diaphragmatic hernia, gastrochisis, and omphalocele. Malrotation is also associated with the heterotaxy syndrome, which is a complex of congenital anomalies including congenital heart malformations, malrotation, biliary atresia, and either asplenia or polysplenia (see Chapter 431.11).

**CLINICAL MANIFESTATIONS**

The reported incidence of malrotation is approximately 1 in 500 infant population. The majority, about 75-85% of patients, present in the 1st yr of life, and more than 50% present within the 1st mo of life, with symptoms of acute or chronic obstruction. Vomiting is the most common symptom in this age group. Infants often present in the 1st wk of life with bilious emesis and acute bowel obstruction. Older infants present with episodes of recurrent abdominal pain that can mimic colic and suggest intermittent volvulus. Malrotation in older children can manifest with recurrent episodes of vomiting and/or abdominal pain. Patients occasionally present with malabsorption or protein-losing enteropathy associated with bacterial overgrowth. Symptoms are caused by intermittent volvulus or duodenal compression by Ladd bands or other adhesive bands affecting the small and large bowel. Approximately 25-50% of adolescents with malrotation are asymptomatic. Adolescents who become symptomatic present with acute intestinal obstruction or history of recurrent episodes of abdominal pain or postprandial bloating and occasional vomiting. Patients of any age with a rotational anomaly can develop acute bowel-threatening volvulus without preexisting symptoms.

An acute presentation of small bowel obstruction in a patient without previous bowel surgery can be the result of volvulus associated with malrotation. This is a life-threatening complication of malrotation, which resembles an acute abdomen or sepsis and is the main reason that symptoms suggesting malrotation should always be investigated. Volvulus occurs when the small bowel twists around the...
Bibliography
superior mesenteric artery leading to vascular compromise of the bowel. The diagnosis may be suggested by ultrasound but is confirmed by contrast radiographic studies. The abdominal plain film is usually nonspecific but might demonstrate a gasless abdomen or evidence of duodenal obstruction with a double-bubble sign. Upper gastrointestinal series is the imaging test of choice and the gold standard in the evaluation and diagnosis of malrotation and volvulus. Normal rotation is indicated by the duodenal C-loop crossing the midline and a duodenojejunal junction located to the left of the spine. Upper gastrointestinal series is the best exam to visualize the malposition of the ligament of Treitz and can also reveal a corkscrew appearance of the small bowel or a duodenal obstruction with a “bird’s beak” appearance of the duodenum. Barium enema usually demonstrates malposition of the cecum but is normal in up to 20% of patients. Ultrasonography can demonstrate the inversion of the superior mesenteric artery and vein. A superior mesenteric vein located to the left of the superior mesenteric artery suggests malrotation. Malrotation with volvulus is suggested by duodenal obstruction, thickened bowel loops to the right of the spine, the superior mesenteric vein coiling around the superior mesenteric artery, and free peritoneal fluid.

**TREATMENT**

Surgical intervention is recommended for any patient with a significant rotational abnormality, regardless of age. If a volvulus is present, surgery is done immediately as an acute emergency, the volvulus is reduced, and the duodenum and upper jejunum are freed of any bands and remain in the right abdominal cavity. The colon is freed of adhesions and placed in the right abdomen with the cecum in the left lower quadrant, usually accompanied by incidental appendectomy. The Ladd procedure may be done laparoscopically for malrotation without volvulus and if gut ischemia is not present, but it is generally done as an open procedure if volvulus is present. The purpose of surgical intervention is to minimize the risk of subsequent volvulus rather than to return the bowel to a normal anatomic configuration. Extensive intestinal ischemia from volvulus can result in short bowel syndrome (see Chapter 330.7).

Intestinal Duplications, Meckel Diverticulum, and Other Remnants of the Omphalomesenteric Duct

331.1 Intestinal Duplication

Chris A. Liacouras

Duplications of the intestinal tract are rare anomalies that consist of well-formed tubular or spherical structures firmly attached to the intestine with a common blood supply. The lining of the duplications resembles that of the gastrointestinal (GI) tract. Duplications are located on the mesenteric border and can communicate with the intestinal lumen. Duplications can be classified into 3 categories: localized duplications, duplications associated with spinal cord defects and vertebral malformations, and duplications of the colon. Occasionally (10-15% of cases), multiple duplications are found.

Localized duplications can occur in any area of the GI tract but are most common in the ileum and jejunum. They are usually cystic or tubular structures within the wall of the bowel. The cause is unknown, but their development has been attributed to defects in recanalization of the intestinal lumen after the solid stage of embryologic development. Duplication of the intestine occurring in association with vertebral and spinal cord anomalies (hemivertebra, anterior spina bifida, band connection between lesion and cervical or thoracic spine) is thought to arise from splitting of the notochord in the developing embryo. Duplication of the colon is usually associated with anomalies of the urinary tract and genitals. Duplication of the entire colon, rectum, anus, and terminal ileum can occur. The defects are thought to be secondary to caudal twinning, with duplication of the hindgut, genital, and lower urinary tracts.

CLINICAL MANIFESTATIONS

Symptoms depend on the size, location, and mucosal lining. Duplications can cause bowel obstruction by compressing the adjacent intestinal lumen, or they can act as the lead point of an intussusception or a site for a volvulus. If they are lined by acid-secreting mucosa, they can cause ulceration, perforation, and hemorrhage of or into the adjacent bowel. Patients can present with abdominal pain, vomiting, palpable mass, or acute GI hemorrhage. Intestinal duplications in the thorax (neuroenteric cysts) can manifest as respiratory distress. Duplications of the lower bowel can cause constipation or diarrhea or be associated with recurrent prolapse of the rectum.

The diagnosis is suspected on the basis of the history and physical examination. Radiologic studies such as barium studies, ultrasonography, CT, and MRI are helpful but usually nonspecific, demonstrating cystic structures or mass effects. Radioisotope technetium scanning can localize ectopic gastric mucosa. The treatment of duplications is surgical resection and management of associated defects.

331.2 Meckel Diverticulum and Other Remnants of the Omphalomesenteric Duct

Melissa Kennedy and Chris A. Liacouras

Meckel diverticulum is the most common congenital anomaly of the GI tract and is caused by the incomplete obliteration of the omphalomesenteric duct during the 7th wk of gestation. The omphalomesenteric duct connects the yolk sac to the gut in a developing embryo and provides nutrition until the placenta is established. Between the 5th and 7th wk of gestation, the duct attenuates and separates from the intestine. Just before this involution, the epithelium of the yolk sac develops a lining similar to that of the stomach. Partial or complete failure of involution of the omphalomesenteric duct results in various residual structures. Meckel diverticulum is the most common of these structures and is the most common congenital GI anomaly, occurring in 2-3% of all infants. A typical Meckel diverticulum is a 3-6 cm outpouching of the ileum along the antimesenteric border 50-75 cm (approximately 2 feet) from the ileocecal valve (Fig. 331-1). The distance from the ileocecal valve depends on the age of the patient. Meckel diverticulum has been conveniently referred to by the “rule of 2s,” which explains the classic presentation of this congenital anomaly. Meckel diverticulum are found in approximately 2% of the general population, are usually located 2 feet proximal to the ileocecal valve and are approximately 2 inches in length, can contain 2 types of ectopic tissue (pancreatic or gastric), generally present before the age
painless rectal bleeding, the presence of a Meckel diverticulum should be suspected because Meckel diverticulum accounts for 50% of all lower GI bleeds in children younger than 2 yr of age. Confirmation of a Meckel diverticulum can be difficult. Plain abdominal radiographs are of no value, and routine barium studies rarely fill the diverticulum. The most sensitive study is a Meckel radionuclide scan, which is performed after intravenous infusion of technetium-99m pertechnetate. The mucus-secreting cells of the ectopic gastric mucosa take up pertechnetate, permitting visualization of the Meckel diverticulum (Fig. 331-2). The uptake can be enhanced with various agents, including cimetidine, ranitidine, glucagon, and pentagastrin. The sensitivity of the enhanced scan is approximately 85%, with a specificity of approximately 95%. A false-negative scan may be seen in anemic patients; although false-positive results are uncommon, they have been reported with intussusception, appendicitis, duplication cysts, arteriovenous malformations, and tumors. Other methods of detection include radiolabeled tagged red blood cell scan (the patient must be actively bleeding), abdominal ultrasound, superior mesenteric angiography, abdominal CT scan, or exploratory laparoscopy. In patients who present with intestinal obstruction or a picture of appendicitis with omphalomesenteric duct remnants, the diagnosis is rarely made before surgery.

The treatment of a symptomatic Meckel diverticulum is surgical excision. A diverticulectomy can be performed safely as either a laparoscopic or open procedure, although most continue to be performed as open procedures. There is significant debate regarding the proper management of an asymptomatic Meckel’s diverticulum and whether excision vs observation is appropriate. However, the risk of serious complications does seem to exceed the operative risk in children younger than 8 yr old.

### Chronic Intestinal Pseudoobstruction

**Kristin N. Fiorino and Chris A. Liacouras**

Chronic intestinal pseudoobstruction comprises a group of disorders characterized as a motility disorder with a primary defect of impaired peristalsis; symptoms are consistent with intestinal obstruction in the absence of mechanical obstruction. The natural history of pseudoobstruction is that of a primary progressive disorder, although there are occasional cases of secondary pseudoobstruction caused by conditions that can transiently or permanently alter bowel motility. The most common cause of acute pseudoobstruction is Ogilvie syndrome (acute pseudoobstruction of the colon). Pseudoobstruction represents a wide spectrum of pathologic disorders from abnormal myoelectric activity to abnormalities of the nerve (intestinal neuropathy) or musculature (intestinal myopathy) of the gut. The organs involved can include the entire gastrointestinal tract or be limited to certain components, although almost always include the small bowel. The distinctive pathologic abnormalities are considered together because of their clinical similarities.

Most congenital forms of pseudoobstruction occur sporadically, although autosomal dominant, autosomal recessive, X-linked, and familial patterns of inheritance have been identified. Patients with autosomal dominant forms of pseudoobstruction have variable expressions of the disease. Acquired pseudoobstruction can follow episodes of acute gastroenteritis, presumably resulting in injury to the myenteric plexus.

In congenital pseudoobstruction, abnormalities of the muscle or nerves can be demonstrated in the majority of cases. In myopathies, the smooth muscle is involved, in which the outer longitudinal muscle layer is replaced by fibrous material. The enteric nervous system is usually altered in neuropathies and may involve disorganized ganglia, hypoganglionosis, or hyperganglionosis. Abnormalities in the interstitial cells of Cajal, the intestinal pacemaker, are classified as mesenchymopathies. In others, mitochondrial defects have been identified. Genetic defects have been identified in the transcription factor SOX10 and the DNA polymerase gamma gene (POLG) in mitochondrialopathies.

### CLINICAL MANIFESTATIONS

More than half the children with congenital pseudoobstruction experience symptoms in the 1st few mo of life. Two-thirds of the infants presenting in the 1st few days of life are born prematurely, and approximately 40% have malrotation of the intestine. In 75% of all affected children, symptoms occur in the 1st yr of life, while the remainder are usually symptomatic within the next several years. The most common symptoms are abdominal distention and vomiting, which are present in 75% of affected infants. Constipation, growth failure, and abdominal pain occur in approximately 60% of patients, and diarrhea in 30-40%. The symptoms wax and wane in the majority of the patients; poor nutrition, psychologic stress, and intercurrent illness tend to exacerbate symptoms. Urinary tract and bladder involvement occurs in 80% of children with myopathic pseudoobstruction and in 20% of those with neuropathic disease. Symptoms can manifest as recurrent urinary tract infection, megacystis, or obstructive symptoms.

### Diagnosis

The diagnosis of pseudoobstruction is based on the presence of compatible symptoms in the absence of mechanical obstruction. Plain abdominal radiographs demonstrate air-fluid levels in the intestine. Neonates with evidence of obstruction at birth may have a microcolon. Contrast studies demonstrate slow passage of barium; water-soluble agents should be considered. Esophageal motility is abnormal in about half the patients. Antroduodenal (small intestinal) motility and gastric emptying studies have abnormal results if the upper gut is involved (Table 332-1). Manometric evidence of a normal migrating motor complex and postprandial activity should redirect the diagnostic evaluation. Anorectal motility is normal and differentiates pseudoobstruction from Hirschsprung disease. Full-thickness intestinal biopsy might show involvement of the muscle layers or abnormalities of the intrinsic intestinal nervous system.

The differential diagnosis is broad and includes such etiologies as Hirschsprung disease, mitochondrial neurogastrointestinal encephalomyopathy, other causes of mechanical obstruction, psychogenic constipation, neurogenic bladder, and superior mesenteric artery syndrome. Secondary causes of ileus or pseudoobstruction, such as hypothyroidism, opiates, scleroderma, Chagas disease, hypokalemia, diabetic neuropathy, amyloidosis, porphyria, angioneurotic edema, mitochondrial disorders, and radiation, must be excluded.

### Treatment

Nutritional support is the mainstay of treatment for pseudoobstruction. Thirty percent to 50% of patients require partial or complete parenteral nutrition. Some patients can be treated with intermittent enteral supplementation, whereas others can maintain themselves on selective oral diets. Prokinetic drugs are generally used although studies have not shown definitive evidence of their efficacy. Isolated gastroparesis can follow episodes of viral gastroenteritis and spontaneously resolves, usually in 6-24 mo. Erythromycin, a motilin receptor agonist, and cisapride, a serotonin 5-HT4 receptor agonist, can enhance

gastric emptying and proximal small bowel motility and may be useful in this select group of patients. Metoclopramide, a prokinetic and antinausea agent, is effective in gastroparesis, although side effects, such as tardive dyskinesia, limit its use. Domperidone, an antipamericergic agent, is a prokinetic agent available though the government in special circumstances. Pain management is difficult and requires a multidisciplinary approach.

Symptomatic small bowel bacterial overgrowth is usually treated with rotated non-absorbable oral antibiotics and/or probiotics. Bacterial overgrowth can be associated with steatorrhea and malabsorption. Octreotide, a long-acting somatostatin analog, has been used in low doses to treat small bowel bacterial overgrowth. Patients with acid peptic symptoms are generally treated with acid suppression. Many benefit from a gastroscopy and some benefit from decompressive enterostomies. Colectomy with ileorectal anastomosis is beneficial if the large bowel is the primary site of the motility abnormality. Bowel transplantation may benefit selected patients.

332.2 Mitochondrial Neurogastrointestinal Encephalomyopathy
Kristin N. Fiorino and Chris A. Liacouras

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a multisystem autosomal recessive disease that initially presents with severe gastrointestinal disturbances; the neurologic manifestations usually occur later in the illness and may initially be subtle or asymptomatic.

MNGIE is caused by a mutation in the nuclear DNA *TYMP* gene encoding thymidine phosphorylase that results in abnormalities in intergenomic communication with resulting instability of mitochondrial DNA. There are at least 50 individual mutations with a poor genotype–phenotype correlation and varying manifestations within each family. Consanguinity is present in 30% of families.

MNGIE affects both males and females and is usually diagnosed in the 2nd and 3rd decade (average age: 18 yr; range: 5 mo-35 yr). Onset is usually around age 12 yr, but there is often a 5-10 yr delay in the diagnosis.

MNGIE initially presents with gastrointestinal symptoms. Severe intestinal dysmotility and gastroparesis is associated with early satiety, postprandial emesis, episodic pseudoobstruction, diarrhea, constipation or fecal withholding, can usually be differentiated from constipation secondary to organic causes on the basis of a history and physical examination. Unlike anorectal malformations and Hirschsprung disease, functional constipation typically starts after the neonatal period. Usually, there is an intentional or subconscious withholding of stool. An acute episode usually precedes the chronic course. The acute episode may be a dietary change from human milk to cow’s milk, secondary to the change in the protein and carbohydrate ratio or an allergy to cow’s milk. The stool becomes firm, smaller, and difficult to pass, resulting in anal irritation and often an anal fissure. In toddlers, coercive or inappropriate early toilet training is a factor that can initiate a pattern of stool retention. In older children, retentive constipation can develop after entering a situation that makes stooling inconvenient such as school. Because the passage of bowel movements is painful, voluntary withholding of feces to avoid the painful stimulus develops.

CLINICAL MANIFESTATIONS

When children have the urge to defecate, typical behaviors include contracting the gluteal muscles by stiffening the legs while lying down, holding onto furniture while standing, or squatting quietly in corners, waiting for the call to stool to pass. The urge to defecate passes as the rectum accommodates to its contents. A vicious cycle of retention develops, as increasingly larger volumes of stool need to be expelled. Caregivers may misinterpret these activities as straining, but it is withholding behavior. There is often a history of blood in the stool noted with the passage of a large bowel movement. Findings suggestive of

332.3 Encopresis and Functional Constipation
Kristin N. Fiorino and Chris A. Liacouras

Constipation is defined as a delay or difficulty in defecation present for 2 wk or longer and significant enough to cause distress to the patient. Another approach to the definition is the Rome Criteria, outlined in Table 332-2. Functional constipation, also known as idiopathic constipation and fecal withholding, can usually be differentiated from constipation secondary to organic causes on the basis of history and physical examination. Unlike anorectal malformations and Hirschsprung disease, functional constipation typically starts after the neonatal period. Usually, there is an intentional or subconscious withholding of stool. An acute episode usually precedes the chronic course. The acute episode may be a dietary change from human milk to cow’s milk, secondary to the change in the protein and carbohydrate ratio or an allergy to cow’s milk. The stool becomes firm, smaller, and difficult to pass, resulting in anal irritation and often an anal fissure. In toddlers, coercive or inappropriate early toilet training is a factor that can initiate a pattern of stool retention. In older children, retentive constipation can develop after entering a situation that makes stooling inconvenient such as school. Because the passage of bowel movements is painful, voluntary withholding of feces to avoid the painful stimulus develops.

Bibliography

underlying pathology include failure to thrive, weight loss, abdominal pain, vomiting, or persistent anal fissure or fistula.

In functional constipation, daytime encopresis is common. Encopresis is defined as voluntary or involuntary passage of feces into inappropriate places at least once a month for 3 consecutive months once a chronologic or developmental age of 4 yr has been reached. Encopresis is not diagnosed when the behavior is exclusively the result of the direct effects of a substance (e.g., laxatives) or a general medical condition (except through a mechanism involving constipation). Subtypes include reteleve encopresis (with constipation and overflow incontinence, representing 65-95% of cases, and nonretentive encopresis (without constipation and overflow incontinence). Nonretentive fecal incontinence is defined as no evidence of fecal retention (impaction), at least 1 episode per week in the previous 2 mo in a child at a developmental age >4 yr, defeation in places inappropriate to the social context and no evidence of anatomic, inflammatory, metabolic, endocrine, or neoplastic process that could explain the symptoms. Encopresis can persist from infancy onward (primary) or can appear after successful toilet training (secondary).

**DIAGNOSIS**

The physical examination often demonstrates a large volume of stool palpated in the suprapubic area; rectal examination demonstrates a dilated rectal vault filled with guaiac-negative stool. Children with encopresis often present with reports of underwear soiling, and many parents initially presume that diarrhea, rather than constipation, is the cause. In retentive encopresis, associated complaints of difficulty with defeation, abdominal or rectal pain, impaired appetite with poor growth, and urinary (day and/or night) incontinence are common. Children often have large bowel movements that obstruct the toilet. There may also be retentive posturing or recurrent urinary tract infections. Nonretentive encopresis is more likely to occur as a solitary symptom and have associated primary underlying psychological etiology. Children with encopresis can present with poor school performance and attendance that is triggered by the scorn and derision from schoolmates because of the child’s offensive odor.

The presence of a hair tuft over the spine or spinal dimple, or failure to elicit a cremasteric reflex or anal wink suggests spinal pathology. A tethered cord is suggested by decreased or absent lower leg reflexes. Spinal cord lesions can occur with overlying skin anomalies. Urinary tract symptoms include recurrent urinary tract infection and enuresis. Children with no evidence of abnormalities on physical examination rarely require radiologic evaluation.

In refractory patients (intractable constipation), specialized testing should be considered to rule out conditions such as hypothyroidism, hypocalcemia, lead toxicity, celiac disease, and allergy testing. Colonic transit studies using radio-opaque markers or scintigraphy techniques may be useful. Selected children can benefit from MRI of the spine to identify an intraspinal process, motility studies to identify underlying myopathic or neuropathic bowel abnormalities, or a contrast enema to identify structural abnormalities. In patients with severe functional constipation, water-soluble contrast enema reveals the presence of a megarectosigmoid (Fig. 332-1). Anorectal motility studies can demonstrate a pattern of paradoxical contraction of the external anal sphincter during defeation, which can be treated by behavior modification and biofeedback. Colonic motility can guide therapy in refractory cases, demonstrating segmental problems that might require surgical intervention.

Complications of reteleve encopresis include day and night urinary incontinence, urinary retention, urinary tract infection, megacystis, and rarely toxic megacolon.

**TREATMENT**

Therapy for functional constipation and encopresis includes patient education, relief of impaction, and softening of the stool. Caregivers must understand that soiling associated with overflow incontinence is associated with loss of normal sensation and not a willful act. There needs to be a focus on adherence with regular postprandial toilet sitting and adoption of a balanced diet. In addition, caregivers should be instructed not to respond to soiling with retaliatory or punitive measures, because children are likely to become angry, ashamed, and resistant to intervention. From the outset, parents should be actively encouraged to reward the child for adherence to a healthy bowel regimen and to avoid power struggles.

If an impaction is present on the initial physical examination, an enema is usually required to clear the impaction while stool softeners are started as maintenance medications. Typical regimens include the use of polyethylene glycol preparations, lactulose, or mineral oil (Tables 332-3 and 332-4). Prolonged use of stimulants such as senna or bisacodyl should be avoided.

Compliance can wane, and failure of this standard treatment approach sometimes requires more intensive intervention. In cases where behavioral or psychiatric problems are evident, involvement of a psychologist or behavioral management (e.g., behavior programs and/or biofeedback). Maintenance therapy is generally continued until a regular bowel pattern has been established and the association of pain with the passage of stool is abolished.

For children with chronic diarrhea and/or irritable bowel syndrome where stress and anxiety play a major role, stress reduction and learning effective coping strategies can play an important role in responding to the encopresis. Relaxation training, stress inoculation, assertiveness training, and/or general stress management procedures can be helpful. Children with spinal problems can be successfully managed with low volumes of fluid through a cecostomy or sigmoid tube.

*Bibliography is available at Expert Consult.*
Hirschsprung disease, or congenital aganglionic megacolon, is a developmental disorder (neurocristopathy) of the enteric nervous system, characterized by the absence of ganglion cells in the submucosal and myenteric plexus. It is the most common cause of lower intestinal obstruction in neonates, with an overall incidence of 1 in 5,000 live births. The male:female ratio for Hirschsprung disease is 4:1 for short-segment disease, and approximately 2:1 with total colonic aganglionosis. Prematurity is uncommon.

There is an increased familial incidence in long-segment disease. Hirschsprung disease may be associated with other congenital defects, including trisomy 21, Joubert syndrome, Goldberg-Shprintzen syndrome, Smith-Lemli-Opitz syndrome, Shah-Waardenburg syndrome, cartilage-hair hypoplasia, multiple endocrine neoplasms 2 syndromes, neurofibromatosis, neuroblastoma, congenital hypoventilation (Ondine's curse), and urogenital or cardiovascular abnormalities. Hirschsprung disease may be associated with other congenital defects, including trisomy 21, Joubert syndrome, Goldberg-Shprintzen syndrome, Smith-Lemli-Opitz syndrome, Shah-Waardenburg syndrome, cartilage-hair hypoplasia, multiple endocrine neoplasms 2 syndromes, neurofibromatosis, neuroblastoma, congenital hypoventilation (Ondine's curse), and urogenital or cardiovascular abnormalities. Hirschsprung disease has been seen in association with microcephaly, mental retardation, abnormal facies, autism, cleft palate, hydrocephalus, and micrognathia.

**PATHOLOGY**

Hirschsprung disease is the result of an absence of ganglion cells in the bowel wall, extending proximally and continuously from the anus for a variable distance. The absence of neural innervation is a consequence of an arrest of neuroblast migration from the proximal to distal bowel. Without the myenteric and submucosal plexus, there is inadequate relaxation of the bowel wall and bowel wall hypertonicity, which can lead to intestinal obstruction.

Hirschsprung disease is usually sporadic, although dominant and recessive patterns of inheritance have been demonstrated in family groups. Genetic defects have been identified in multiple genes that encode proteins of the RET signaling pathway (RET, GDNF, and NTN) and involved in the endothelin (EDN) type B receptor pathway (EDNRB, EDN3, and EVE-1). Syndromic forms of Hirschsprung disease have been associated with the LICAM, SOX10, and ZFHX1B (formerly SIP1) genes.

The aganglionic segment is limited to the rectosigmoid in 80% of patients. Approximately 10-15% of patients have long-segment disease, defined as disease proximal to the sigmoid colon. Total bowel aganglionosis is rare and accounts for approximately 5% of cases. Observed histologically is an absence of Meissner's and Auerbach's plexuses and hypertrophied nerve bundles with high concentrations of acetylcholinesterase between the muscular layers and in the submucosa.

**CLINICAL MANIFESTATIONS**

Hirschsprung disease is usually diagnosed in the neonatal period secondarily to a distended abdomen, failure to pass meconium, and/or bilious emesis or aspirates with feeding intolerance. In 99% of healthy full-term infants, meconium is passed within 48 hr of birth. Hirschsprung disease should be suspected in any full-term infant (the disease is unusual in preterm infants) with delayed passage of stool. Some neonates pass meconium normally but subsequently present with a history of chronic constipation. Failure to thrive with hypoproteinemina from protein-losing enteropathy is a less common presentation because Hirschsprung disease is usually recognized early in the course of the illness. Breastfed infants might not suffer disease as severe as formula-fed infants.

Failure to pass stool leads to dilation of the proximal bowel and abdominal distention. As the bowel dilates, intraluminal pressure...
The digestive system

Distention initiates relaxation of the internal anal sphincter in response to rectal distention. In patients with Hirschsprung disease, the internal anal sphincter fails to relax in response to rectal distention. Although the sensitivity and specificity can vary widely, in experienced hands, the test can be quite sensitive. The test, however, can be technically difficult to perform in young infants. A normal response in the course of manometric evaluation precludes a diagnosis of Hirschsprung disease; an equivocal or paradoxical response requires a repeat motility or rectal biopsy.

Increases, resulting in decreased blood flow and deterioration of the mucosal barrier. Stasis allows proliferation of bacteria, which can lead to enterocolitis (Clostridium difficile, Staphylococcus aureus, anaerobes, coliforms) with associated diarrhea, abdominal tenderness, sepsis and signs of bowel obstruction. Early recognition of Hirschsprung disease before the onset of enterocolitis is essential in reducing morbidity and mortality.

Hirschsprung disease in older patients must be distinguished from other causes of abdominal distention and chronic constipation (Table 332-5 and Fig. 332-2). The history often reveals constipation starting in infancy that has responded poorly to medical management. Fecal incontinence, fecal urgency, and stool-withholding behaviors are usually not present. The abdomen is tympanitic and distended, with a large fecal mass palpable in the left lower abdomen. Rectal examination demonstrates a normally placed anus that easily allows entry of the finger but feels snug. The rectum is usually empty of feces, and when the finger is removed, there may be an explosive discharge of foul-smelling feces and gas. The stools, when passed, can consist of small pellets, be ribbon-like, or have a fluid consistency, unlike the large stools seen in patients with functional constipation. Intermittent attacks of intestinal obstruction from retained feces may be associated with pain and fever. Urinary retention with enlarged balder or hydronephrosis can occur secondary to urinary compression.

In neonates, Hirschsprung disease must be differentiated from meconium plug syndrome, meconium ileus, and intestinal atresia. In older patients, the Currarino triad must be considered, which includes anorectal malformations (ectopic anus, anal stenosis, imperforate anus), sacral bone anomalies (hypoplasia, poor segmentation), and presacral anomaly (anterior meningoceles, teratoma, cyst).

**DIAGNOSIS**

Rectal suction biopsy is the gold standard for diagnosing Hirschsprung disease. The biopsy material should contain an adequate amount of submucosa to evaluate for the presence of ganglion cells. To avoid obtaining biopsies in the normal area of hypoganglionosis, which ranges from 3-17 mm in length, the suction rectal biopsy should be obtained no closer than 2 cm above the dentate line. The biopsy specimen should be stained for acetylcholinesterase to facilitate interpretation. Patients with aganglionosis demonstrate a large number of hypertrophied nerve bundles that stain positively for acetylcholinesterase with an absence of ganglion cells. Calretinin staining may provide a diagnosis of Hirschsprung disease when acetylcholinesterase staining may not be sufficient.

Anorectal manometry evaluates the internal anal sphincter while a balloon is distended in the rectum. In healthy individuals, rectal distention initiates relaxation of the internal anal sphincter in response to rectal distention. In patients with Hirschsprung disease, the internal anal sphincter fails to relax in response to rectal distention. Although the sensitivity and specificity can vary widely, in experienced hands, the test can be quite sensitive. The test, however, can be technically difficult to perform in young infants. A normal response in the course of manometric evaluation precludes a diagnosis of Hirschsprung disease; an equivocal or paradoxical response requires a repeat motility or rectal biopsy.

![Figure 332-2 Lateral view of a barium enema in a 3 yr old girl with Hirschsprung disease. The aganglionic distal segment is narrow, with distended normal ganglionic bowel above it.](image-url)
An unprepared contrast enema is most likely to aid in the diagnosis in children older than 1 mo of age because the proximal ganglionic segment might not be significantly dilated in the 1st few wk of life. Classic findings are based on the presence of an abrupt narrow transition zone between the normal dilated proximal colon and a smaller-caliber obstructed distal ganglionic segment. In the absence of this finding, it is imperative to compare the diameter of the rectum to that of the sigmoid colon, because a rectal diameter that is the same as or smaller than the sigmoid colon suggests Hirschsprung disease. Radiologic evaluation should be performed without preparation to prevent transient dilation of the aganglionic segment. As many as 10% of newborns with Hirschsprung disease have a normal contrast study. Twenty-four-hour delayed films are helpful in showing retained contrast (see Fig. 332.2). If significant barium is still present in the colon, it increases the suspicion of Hirschsprung disease even if a transition zone is not identified. Barium enema examination is useful in determining the extent of aganglionosis before surgery and in evaluating other diseases that manifest as lower bowel obstruction in a neonate. Full-thickness rectal biopsies can be performed at the time of surgery to confirm the diagnosis and level of involvement.

**TREATMENT**

Once the diagnosis is established, the definitive treatment is operative intervention. Previously, a temporary ostomy was placed and definitive surgery was delayed until the child was older. Currently, many infants undergo a primary pull-through procedure except if there is associated enterocolitis or other complications, when a decompressing ostomy is usually required.

There are 3 basic surgical options. The first successful surgical procedure, described by Swenson, was to excise the aganglionic segment and anastomose the normal proximal bowel to the rectum 1-2 cm above the dentate line. The operation is technically difficult and led to the development of 2 other procedures. Duhamel described a procedure to create a neorectum, bringing down normally innervated bowel behind the aganglionic rectum. The neorectum created in this procedure has an anterior aganglionic segment with normal sensation and a posterior ganglionic segment with normal propulsion. The endorectal pull-through procedure described by Soave involves stripping the mucosa from the aganglionic rectum and bringing normally innervated colon through the residual muscular cuff, thus bypassing the abnormal bowel from within. Advances in techniques have led to successful laparoscopic single-stage endorectal pull-through procedures, which are the treatment of choice.

In ultrashort-segment Hirschsprung disease, also known as anal achalasia, the aganglionic segment is limited to the internal sphincter. The clinical symptoms are similar to those of children with functional constipation. Ganglion cells are present on rectal suction biopsy, but the anorectal manometry is abnormal, with failure of relaxation of the internal sphincter in response to rectal distention. Current treatment, although controversial, includes anal bulbotomy injection to relax the anal sphincter and anorectal myectomy if indicated.

Long-segment Hirschsprung disease involving the entire colon and, at times, part of the small bowel presents a difficult problem. Anorectal manometry and rectal suction biopsy demonstrate findings of Hirschsprung disease, but radiologic studies are difficult to interpret because a colonic transition zone cannot be identified. The extent of aganglionosis can be determined accurately by biopsy at the time of laparotomy. When the entire colon is aganglionic, often together with a length of terminal ileum, ileal-anal anastomosis is the treatment of choice, preserving part of the aganglionic colon to facilitate water absorption, which helps the stools to become firm.

The prognosis of surgically treated Hirschsprung disease is generally satisfactory; the great majority of patients achieve fecal continence. Long-term postoperative problems include constipation, recurrent enterocolitis, stricture, prolapse, perianal abscesses, and fecal soiling. Some children require myectomy or a redo pull-through procedure.

**332.5 Intestinal Neuronal Dysplasia**

**Kristin N. Fiorino and Chris A. Liacouras**

Intestinal neuronal dysplasia (IND) describes different quantitative (hypo- or hyperganglionosis) and qualitative (immature or heterotopic ganglion cells) abnormalities of the myenteric and/or submucosal plexus. The typical histology is that of hyperganglionosis and giant ganglia. Type A occurs very rarely and is characterized by congenital aplasia or hypoplasia of the sympathetic innervation. Patients present early in the neonatal period with episodes of intestinal obstruction, diarrhea, and bloody stools. Type B, which accounts for more than 95% of cases, is characterized by malformation of the parasympathetic submucous and myenteric plexus with giant ganglia and thickened nerve fibers, increased acetylcholinesterase staining, and isolated ganglion cells in the lamina propria. IND type B mimics Hirschsprung disease, and patients present with chronic constipation.

Clinical manifestations include abdominal distention, constipation, and enterocolitis. Various lengths of bowel may be affected from segmental to the entire intestinal tract. IND has been observed in a isolated form and proximal to an aganglionic segment. Other intra- and extraintestinal manifestations are present in patients with IND. It has been reported in all age groups, most commonly in infancy, but is also seen in adults who have had constipation not dating back to childhood.

Associated diseases and conditions include Hirschsprung disease, prematurity, small left colon syndrome, and meconium plug syndrome. Studies have identified a deficiency in substance P in patients with IND. No mutations in the coding regions of the RET, GDNF, EDNRB, or EDN3 genes have been identified.

Management includes that for functional constipation and, if unsuccessful, surgery is indicated.

**332.6 Superior Mesenteric Artery Syndrome (Wilkie Syndrome, Cast Syndrome, Arteriomesenteric Duodenal Compression Syndrome)**

**Andrew Chu and Chris A. Liacouras**

Superior mesenteric artery syndrome results from compression of the 3rd duodenal segment by the artery against the aorta. Malnutritious or catabolic states may cause mesenteric fat depletion, which collapses the duodenum within a narrowed aortomesenteric angle. Other etiologies include extraabdominal compression (e.g., body cast) and mesenteric tension, as can occur from ileoanal pouch anastomosis.

Symptoms include intermittent epigastric pain, anorexia, nausea, and vomiting. Risk factors include thin body habitus, prolonged bed rest, abdominal surgery, and exaggerated lumbar lordosis. Onset can be within weeks of a trigger, but some patients have chronic symptoms that evade diagnosis. A classic example is an underweight adolescent who begins vomiting 1-2 wk following scoliosis surgery. Recognition may be delayed in the context of an eating disorder.

The diagnosis is established radiologically by demonstrating a duodenal cutoff just right of midline along with proximal duodenal dilatation, with or without gastric dilation. Although the upper gastrointestinal series remains a mainstay, modalities including CT, MR angiography, or ultrasound may be more appropriate if there is concern for other etiologies like malignancy. Upper endoscopy should be considered to rule out intraluminal pathology.

Treatment focuses on obstructive relief, nutritional rehabilitation, and correction of associated fluid and electrolyte abnormalities. Lateral or prone positioning can shift the duodenum away from obstructing structures and allow resumption of oral intake. In such cases, prokinetic agents (e.g., erythromycin) may be helpful. If repositioning is
Bibliography

Bibliography

Bibliography
unsuccessful, patients require nasojejunal enteral nutrition past the obstruction or parenteral nutrition if this is not tolerated. Patients with refractory courses may require surgery to bypass the obstruction.

_Bibliography is available at Expert Consult._
Bibliography
Ileus is the failure of intestinal peristalsis caused by loss of coordinated gut motility without evidence of mechanical obstruction. In children, it is most often associated with abdominal surgery or infection (gastroenteritis, pneumonia, peritonitis). Ileus also accompanies metabolic abnormalities (e.g., uremia, hypokalemia, hypercalcemia, hypermagnesemia, acidosis) or administration of certain drugs, such as opiates, vincristine, and antimotility agents such as loperamide when used during gastrointestinal. Ileus manifests with nausea, vomiting, feeding intolerance, abdominal distention with associated pain, and delayed passage of stool and bowel gas. Bowel sounds are minimal or absent, in contrast to early mechanical obstruction, when they are hyperactive. Abdominal radiographs demonstrate multiple air–fluid levels throughout the abdomen. Serial radiographs usually do not show progressive distention as they do in mechanical obstruction. Contrast radiographs, if performed, demonstrate slow movement of barium through a patent lumen. Ileus after abdominal surgery generally resolves within 72 hr.

Treatment involves correcting the underlying abnormality, supportive care of comorbidities, and mitigation of iatrogenic contributions. Electrolyte abnormalities should be identified and corrected, and narcotic agents, when used, should be weaned as tolerated. Nasogastric decompression can relieve recurrent vomiting or abdominal distention associated with pain; resultant fluid losses should be corrected with isotonic crystalloid solution. Prokinetic agents such as erythromycin are not routinely recommended. Selective peripheral opioid antagonists such as methylnaltrexone hold promise in decreasing postoperative ileus, but pediatric data are lacking.

Bibliography is available at Expert Consult.

Adhesions are fibrous tissue bands that result from peritoneal injury. They can constrict hollow organs and are a major cause of postoperative small bowel obstruction. Most remain asymptomatic, but problems can arise anytime after the 2nd postoperative week to years after surgery, regardless of surgical extent. In one study, the 5-year readmission risk because of adhesions varied by operative region (2.1% for colon to 9.2% for ileum) and procedure (0.3% for appendectomy to 25% for ileostomy formation/closure). The overall risk was 5.3% excluding appendectomy and 1.1% when appendectomy was included. The diagnosis is suspected in patients with abdominal pain, constipation, emesis, and a history of intraperitoneal surgery. Nausea and vomiting quickly follow onset of pain. Initially, bowel sounds are hyperactive, and the abdomen is flat. Subsequently, bowel sounds disappear, and bowel dilation can cause abdominal distention. Fever and leukocytosis suggest bowel necrosis and peritonitis. Plain radiographs demonstrate obstructive features, and a CT scan or contrast studies may be needed to define the etiology.

Management includes nasogastric decompression, intravenous fluid resuscitation, and broad-spectrum antibiotics in preparation for surgery. Nonoperative intervention is contraindicated unless a patient is stable with obvious clinical improvement. In children with repeated obstruction, fibrin-glued plication of adjacent small bowel loops can reduce the risk of recurrent problems. Long-term complications include female infertility, failure to thrive, and chronic abdominal and/or pelvic pain.

Bibliography is available at Expert Consult.

Intussusception occurs when a portion of the alimentary tract is telescoped into an adjacent segment. It is the most common cause of intestinal obstruction between 5 mo and 3 yr of age and the most common abdominal emergency in children younger than 2 yr. Sixty percent of patients are younger than 1 yr of age, and 80% of the cases occur before age 24 mo; it is rare in neonates. The incidence varies from 1 to 4 per 1,000 live births. The male:female ratio is 3:1. Many small bowel–small bowel and a few small bowel–colonic intussusceptions reduce spontaneously; if left untreated, ileal–colonic intussusception may lead to intestinal infarction, perforation, peritonitis, and death.

**ETIOLOGY AND EPIDEMIOLOGY**

Approximately 90% of cases of intussusception in children are idiopathic. The seasonal incidence has peaks in fall and winter. Correlation with prior or concurrent respiratory adenovirus (type C) infection has been noted, and the condition can complicate otitis media, gastroenteritis, Henoch-Schönlein purpura, or other upper respiratory tract infections. The risk of intussusception was increased in infants 1 yr of age or younger after receiving a tetravalent rhesus-human reassortant rotavirus vaccine within 2 wk of immunization. The Advisory Committee on Immunization Practices no longer recommends this vaccine, and it is no longer available. Although rotavirus produces an enterotoxin, there is no association between wild-type human rotavirus and intussusception. The currently approved rotavirus vaccines are associated with a slightly increased risk of intussusception.

It is postulated that gastrointestinal infection or the introduction of new food proteins results in swollen Peyer patches in the terminal ileum. Lymphoid nodular hyperplasia is another related risk factor. Prominent mounds of lymph tissue lead to mucosal prolapse of the ileum into the colon, thus causing an intussusception. In 2-8% of patients, recognizable lead points for the intussusception are found, such as a Meckel diverticulum, intestinal polyp, neurofibroma, intestinal duplication cysts, inverted appendix stump, leiomyomas, hamartomas, ectopic pancreatic tissue, anastomotic suture line, enterostomy tube, postertransplant lymphoproliferative disease, hemangioma, or malignant conditions such as lymphoma, or Kaposi sarcoma. Lead points are more common in children older than 2 yr of age; the older the child, the higher the risk of a lead point. In adults, lead points are present in 90%. Intussusception can complicate mucosal hemorrhage, as in Henoch-Schönlein purpura, idiopathic thrombocytopenic purpura, or hemophilia. Cystic fibrosis, celiac disease, and Crohn disease are other risk factors. Postoperative intussusception is ileocecal and usually occurs within several days of an abdominal operation. Intrauterine intussusception may be associated with the development of intestinal atresia. Intussusception in premature infants is rare.
Bibliography

Bibliography
Ileal–ileal intussusception may be more common than previously believed, is often idiopathic or associated with Henoch-Schönlein purpura, and usually resolves spontaneously.

**PATHOLOGY**

Intussusceptions are most often ileocolic, less commonly cecocolic, and occasionally ileal. Very rarely, the appendix forms the apex of an intussusception. The upper portion of bowel, the intussuscipiens, invaginates into the lower, the intussusceptum, pulling its mesentery along with it into the enveloping loop. Constriction of the mesentery obstructs venous return; engorgement of the intussusceptum follows, with edema, and bleeding from the mucosa leads to a bloody stool, sometimes containing mucus. The apex of the intussusception can extend into the transverse, descending, or sigmoid colon, even to and through the anus in neglected cases. This presentation must be distinguished from rectal prolapse. Most intussusceptions do not strangulate the bowel within the 1st 24 hr but can eventuate in intestinal gangrene and shock.

**CLINICAL MANIFESTATIONS**

In typical cases, there is sudden onset, in a previously well child, of severe paroxysmal colicky pain that recurs at frequent intervals and is accompanied by straining efforts with legs and knees flexed and loud cries. The infant may initially be comfortable and play normally between the paroxysms of pain; but if the intussusception is not reduced, the infant becomes progressively weaker and lethargic. At times, the lethargy is disproportionate to the abdominal signs. Eventually, a shock-like state, with fever and peritonitis, can develop. The pulse becomes weak and thready; the respirations become shallow and grunting, and the pain may be manifested only by moaning sounds. Vomiting occurs in most cases and is usually more frequent in the early phase. In the later phase, the vomitus becomes bile stained. Stools of normal appearance may be evacuated in the 1st few hr of symptoms. After this time, fecal excretions are small or more often do not occur, and little or no flatus is passed. Blood is generally passed in the 1st 12 hr, but at times not for 1-2 days, and infrequently not at all; 60% of infants pass a stool containing red blood and mucus, the currant jelly stool. Some patients have only irritability and alternating or progressive lethargy. The classic triad of pain, a palpable sausage-shaped abdominal mass, and bloody or currant jelly stool is seen in <30% of patients with intussusception. The combination of paroxysmal pain, vomiting and a palpable abdominal mass has a positive predictive value of ~90%; the presence of rectal bleeding increases this to approximately 100%.

Palpation of the abdomen usually reveals a slightly tender sausage-shaped mass, sometimes ill defined, which might increase in size and firmness during a paroxysm of pain and is most often in the right upper abdomen, with its long axis cephalocaudal. If it is felt in the epigastrium, the long axis is transverse. Approximately 30% of patients do not have a palpable mass. The presence of bloody mucus on rectal examination supports the diagnosis of intussusception. Abdominal distention and tenderness develop as intestinal obstruction becomes more acute. On rare occasions, the advancing intestine prolapses through the anus. This prolapse can be distinguished from prolapse of the rectum by the separation between the protruding intestine and the rectal wall, which does not exist in prolapse of the rectum.

Ileoileal intussusception in children younger than 2 yr can have a less-typical clinical picture, the symptoms and signs being chiefly those of small intestinal obstruction; these often resolve without treatment. Recurrent intussusception is noted in 5-8% and is more common after hydrostatic than surgical reduction. Chronic intussusception, in which the symptoms exist in milder form at recurrent intervals, is more likely to occur with or after acute enteritis and can arise in older children as well as in infants.

**DIAGNOSIS**

When the clinical history and physical findings suggest intussusception, an ultrasound is typically performed. A plain abdominal radiograph might show a density in the area of the intussusception. Screening ultrasounds for suspected intussusception increases the yield of diagnostic or therapeutic enemas and reduces unnecessary radiation exposure in children with negative ultrasound examinations. The diagnostic findings of intussusception on ultrasound include a tubular mass in longitudinal views and a doughnut or target appearance in transverse images (Fig. 333-1). Ultrasound has a sensitivity of approximately 98-100% and a specificity of approximately 98% in diagnosing intussusception. Air, hydrostatic (saline), and, less often, water-soluble contrast enemas have replaced barium examinations. Contrast enemas demonstrate a filling defect or cupping in the head of the contrast media where its advance is obstructed by the intussusceptum (Fig. 333-2). A central linear column of contrast media may be visible in the compressed lumen of the intussusceptum, and a thin rim of contrast may be seen trapped around the invaginating intestine in the folds of mucosa within the intussusciens (coiled-spring sign), especially after evacuation. Retrogression of the intussusceptum under pressure and visualized on x-ray or ultrasound documents successful reduction. Air reduction is associated with fewer complications and lower radiation exposure than traditional contrast hydrostatic techniques.

**DIFFERENTIAL DIAGNOSIS**

It may be particularly difficult to diagnose intussusception in a child who already has gastroenteritis; a change in the pattern of illness, in the character of pain, or in the nature of vomiting or the onset of rectal bleeding should alert the physician. The bloody stools and abdominal cramps that accompany enterocolitis can usually be differentiated from intussusception because in enterocolitis the pain is less severe and less regular, there is diarrhea, and the infant is recognizable ill between pains. Bleeding from a Meckel diverticulum is usually painless. Joint symptoms, purpura, or hematuria usually but not invariably accompany the intestinal hemorrhage of Henoch-Schönlein purpura. Because intussusception can be a complication of this disorder, ultrasonography may be needed to distinguish the conditions.
Corticosteroids may reduce the frequency of recurrent intussusception. Repeated reducible episodes caused by lymphonodular hyperplasia may respond to treatment of identifiable food allergies if present. A single recurrence of intussusception can usually be reduced radiologically. In patients with multiple ileal–colonic recurrences, a lead point should be suspected and laparoscopic surgery considered. It is unlikely that an intussusception caused by a lesion such as lymphosarcoma, polyp, or Meckel diverticulum will be successfully reduced by radiologic intervention. With adequate surgical management, laparoscopic reduction carries a very low mortality.

Bibliography is available at Expert Consult.

333.4 Closed-Loop Obstructions
Andrew Chu and Chris A. Liacouras

Closed-loop obstructions (i.e., internal hernia) result from bowel loops that enter windows created by mesenteric defects or adhesions and become trapped. Vascular engorgement of the strangulated bowel results in intestinal ischemia and necrosis unless promptly relieved. Prior abdominal surgery is an important risk factor. Symptoms include abdominal pain, distention, and bilious emesis. Symptoms can be intermittent if the herniated bowel slides in and out of the defect. Peritoneal signs suggest ischemic bowel. Plain radiographs demonstrate signs of small bowel obstruction or free air if the bowel has perforated. CT scan can identify and delineate internal hernias. Supportive management includes intravenous fluids, antibiotics, and nasogastric decompression. Prompt surgical relief of the obstruction is indicated to prevent bowel necrosis.

Bibliography is available at Expert Consult.

It is important in patients with cystic fibrosis to distinguish intussusception from distal intestinal obstruction syndrome. Distal intestinal obstruction syndrome requires antegrade treatment, which would be harmful if there was an intussusception.

TREATMENT
Reduction of an acute intussusception is an emergency procedure and should be performed immediately after diagnosis in preparation for possible surgery. In patients with prolonged intussusception and signs of shock, peritoneal irritation, intestinal perforation, or pneumatosis intestinialis, hydrostatic reduction should not be attempted.

The success rate of radiologic hydrostatic reduction under fluoroscopic or ultrasonic guidance is approximately 80-95% in patients with ileocolic intussusception. Spontaneous reduction of intussusception occurs in approximately 4-10% of patients. Bowel perforations occur in 0.5-2.5% of attempted barium and hydrostatic (saline) reductions. The perforation rate with air reduction is 0.1-0.2%. Surgical reduction is indicated in the presence of refractory shock, suspected bowel necrosis or perforation, peritonitis, and multiple recurrences (suspected lead point).

An ileoileal intussusception is best demonstrated by abdominal ultrasonography. Reduction by instillation of contrast agents, saline, or air might not be possible. Such intussusceptions can develop insidiously after bowel surgery and require reoperation if they do not spontaneously reduce. Ileoileal disease is common with Henoch-Schönlein purpura and other unidentifiable disorders and usually resolves without the need for any specific treatment. If manual operative reduction is impossible or the bowel is not viable, resection of the intussusception is necessary, with end-to-end anastomosis.

PROGNOSIS
Untreated intussusception in infants is usually fatal; the chances of recovery are directly related to the duration of intussusception before reduction. Most infants recover if the intussusception is reduced in the 1st 24 hr, but the mortality rate rises rapidly after this time, especially after the 2nd day. Spontaneous reduction during preparation for operation is not uncommon.

The recurrence rate after reduction of intussusceptions is approximately 10%, and after surgical reduction it is 2-5%; none has recurred after surgical resection. Most recurrences occur within 72 hr of reduction.

334.1 Foreign Bodies in the Stomach and Intestine

Judith R. Kelsen and Chris A. Liacouras

Once in the stomach, 95% of all ingested objects pass without difficulty through the remainder of the gastrointestinal tract. Perforation after ingestion of a foreign body is estimated to be <1% of all objects ingested. Perforation tends to occur in areas of physiologic sphincters (pylorus, ileocecal valve), acute angulation (duodenal sweep), congenital gut malformations (webs, diaphragms, diverticula), or areas of previous bowel surgery.

Most patients who ingest foreign bodies are between the ages of 6 mo and 6 yr. Coins are the most commonly ingested foreign body in children, and meat or food impactions are the most common accidental foreign body in adolescents and adults. Patients with nonfood foreign bodies often describe a history of ingestion. Young children might have a witness to ingestion. Immediate concerns are what is the foreign body, location of the foreign body, what is the size of the foreign body, and the time that the ingestion occurred. Approximately 90% of foreign bodies are opaque. Radiologic examination is routinely performed to determine the type, number, and location of the suspected objects. Contrast radiographs may be necessary to demonstrate some objects, such as plastic parts or toys.
Conservative management is indicated for most foreign bodies that have passed through the esophagus and entered the stomach. Most objects pass through the intestine in 4–6 days, although some take as long as 3–4 wk. While waiting for the object to pass, parents are instructed to continue a regular diet and to observe the stools for the appearance of the ingested object. Cathartics should be avoided. Exceptionally long or sharp objects are usually monitored radiologically. Parents or patients should be instructed to report abdominal pain, vomiting, persistent fever, and hematemesis or melena immediately to their physicians. Failure of the object to progress within 3–4 wk seldom implies an impeding perforation but may be associated with a congenital malformation or acquired bowel abnormality.

Certain objects pose more risk than others. In cases of sharp foreign bodies, such as straight pins, weekly assessments are required. Surgical removal is necessary if the patient develops symptoms or signs of obstruction or perforation or if the foreign body fails to progress for several weeks. Small magnets used to secure earrings or parts of toys are associated with bowel perforation. Whereas a single magnet in the stomach may not require intervention in a asymptomatic child, a magnet in the esophagus requires immediate removal. When the multiple magnets disperse after ingestion, they may be attracted to each other across bowel wall, leading to pressure necrosis and perforation (Fig. 334-1). Inexpensive toy medallions containing lead can lead to lead toxicity. Newer coins can also decompose when subjected to prolonged acid exposure. Unless multiple coins are ingested; however, the metals released are unlikely to pose a clinical risk.

Ingestion of batteries rarely leads to problems, but symptoms can arise from leakage of alkali or heavy metal (mercury) from battery degradation in the gastrointestinal tract. Batteries can also generate electrical current and thereby cause low-voltage electrical burns to the intestine. If patients experience symptoms such as vomiting or abdominal pain, if a large-diameter battery (>20 mm in diameter) remains in the stomach for longer than 48 hr, or if a lithium battery is ingested, the battery should be removed. Batteries larger than 15 mm that do not pass the pylorus within 48 hr are less likely to pass spontaneously and generally require removal. In children younger than 6 yr of age, batteries larger than 15 mm are not likely to pass spontaneously and should be removed endoscopically. If the patient develops peritoneal signs, surgical removal is required. Batteries beyond the duodenum pass per rectum in 85% within 72 hr. The battery should be identified by size and imprint code or by evaluation of a duplicate measurement of the battery compartment. The National Button Battery Ingestion Hotline (202-625-3333) can be called for help in identification. The Poison Control Center (800-222-1222) can be called as well for ingestion of batteries and caustic materials. Lithium batteries result in more prolonged acid exposure. Unless multiple coins are ingested; however, the metals released are unlikely to pose a clinical risk.

Ingestion of magnets poses a danger to children. The number of magnets is thought to be critical. If a single magnet is ingested, there is the least likelihood of complications. If 2 or more magnets are ingested, the magnetic poles are attracted to each other and create the risk of obstruction, fistula development, and perforation. Endoscopic retrieval is emergent after films are taken when multiple magnets are ingested. Abdominal pain or peritoneal signs require urgent surgical intervention. If all magnets are located in the stomach, immediate endoscopic removal is indicated. If the ingestion occurred greater than 12 hr prior to evaluation, General Surgery should be consulted. If the magnets are beyond the stomach and the patient is symptomatic, General Surgery should be consulted. If the patient is asymptomatic, endoscopic or colonoscopic removal may be considered along with a surgical evaluation.

Lead-based foreign bodies can cause symptoms from lead intoxication. Early endoscopic removal is indicated of an object suspected to contain lead. A lead level should be obtained.

Water-absorbing polymer balls (beads) can expand to approximately 400 times its starting size and if ingested may produce intestinal obstruction. Initially of a small diameter, they pass the pylorus only to rapidly enlarge in the small intestine. Surgical removal is indicated.

Children occasionally place objects in their rectum. Small blunt objects usually pass spontaneously, but large or sharp objects typically need to be retrieved. Adequate sedation is essential to relax the anal sphincter before attempted endoscopic or speculum removal. If the object is proximal to the rectum, observation for 12–24 hr usually allows the object to descend into the rectum.

### 334.2 Bezoars

**Judith R. Kelsen and Chris A. Liacouras**

A bezoar is an accumulation of exogenous matter in the stomach or intestine. They are predominantly composed of food or fiber. Most bezoars have been found in females with underlying personality problems or in neurologically impaired persons. Patients who have undergone abdominal surgery are at higher risk for the development of bezoars. The peak age at onset of symptoms is the 2nd decade of life.

Bezoars are classified on the basis of their composition. **Trichobezoars** are composed of the patient's own hair. It is most frequently it is a complication of the psychiatric disorders trichotillomania and the most severe form is known as Rapunzel syndrome. **Phytobezoars** are

composed of a combination of plant and animal material, and gastric phytobezoars are the most common in patients with poor motility. Lactobezoars were previously found most often in premature infants and can be attributed to the high casein or calcium content of some premature formulas. Swallowed chewing gum can occasionally lead to a bezoar.

Trichobezoars can become large and form casts of the stomach; they can enter into the proximal duodenum. They manifest as symptoms of gastric outlet or partial intestinal obstruction including vomiting, anorexia, and weight loss. Patients might complain of abdominal pain, distention, and severe halitosis. Physical examination can demonstrate patchy baldness and a firm mass in the left upper quadrant. Patients occasionally have iron-deficiency anemia, hypoproteinemia, or steatorrhea caused by an associated chronic gastritis. Phytobezoars manifest in a similar manner. Detached segments of the bezoar or trichobezoar can migrate to the small intestine as a “satellite masses” and result in small bowel obstruction.

An abdominal plain film can suggest the presence of a bezoar, which can be confirmed on ultrasound or CT examination. On CT a bezoar appears a nonhomogeneous, nonenhancing mass within the lumen of the stomach or intestine. Oral contrast circumscribes the mass.

Bezoars in the stomach can usually be removed endoscopically. If endoscopy is unsuccessful, surgical intervention may be needed. Lactobezoars usually resolve when feedings are withheld for 24-48 hr. Coca-Cola has been used as a dissolution therapy for gastric phytobezoar and has been shown to be effective when used with endoscopy.

Sunflower seed bezoars are reported to cause rectal pain and constipation as a result of the seed shells being associated with fecal impaction. Endoscopic removal is indicated, as these bezoars are refractory to enema or lavage management.

| Cameron ulcer (gastric ulcer where a hiatal hernia passes through the diaphragmatic hiatus) |
| True idiopathic ulcer                                        |

*Requires search for other specific causes.

NSAID, nonsteroidal anti-inflammatory drug.

Peptic ulcer disease, the end result of inflammation caused by an imbalance between cytoprotective and cytotoxic factors in the stomach and duodenum, manifests with varying degrees of gastritis or frank ulceration. The pathogenesis of peptic ulcer disease is multifactorial, but the final common pathway for the development of ulcers is the action of acid and pepsin-laden contents of the stomach on the gastric and duodenal mucosa and the inability of mucosal defense mechanisms to allay those effects. Abnormalities in the gastric and duodenal mucosa can be visualized on endoscopy, with or without histologic changes. Deep mucosal lesions that disrupt the muscularis mucosa of the gastric or duodenal wall define *peptic ulcers*. Gastric ulcers are generally located on the lesser curvature of the stomach, and 90% of duodenal ulcers are found in the duodenal bulb. Despite the lack of large population-based pediatric studies, rates of peptic ulcer disease in childhood appear to be low. Large pediatric centers anecdotally report an incidence of 5-7 children with gastric or duodenal ulcers per 2,500 hospital admissions each year.

Ulcers in children can be classified as *primary* peptic ulcers, which are chronic and more often duodenal, or *secondary*, which are usually more acute in onset and are more often gastric (Table 335-1). Primary ulcers are most often associated with *Helicobacter pylori* infection; idiopathic primary peptic ulcers account for up to 20% of duodenal ulcers in children. Secondary peptic ulcers can result from stress caused by sepsis, shock, or an intracranial lesion (Cushing ulcer), or in response to a severe burn injury (Curling ulcer). Secondary ulcers are often the result of using aspirin or nonsteroidal antiinflammatory drugs (NSAIDs); hypersecretory states like Zollinger-Ellison syndrome (see Chapter 335.1), short bowel syndrome, and systemic mastocytosis are rare causes of peptic ulceration.

**PATHOGENESIS**

**Acid Secretion**

By 3-4 yr of age, gastric acid secretion approximates adult values. Acid initially secreted by the oxyntic cells of the stomach has a pH of approximately 0.8, whereas the pH of the stomach contents is 1-2. Excessive acid secretion is associated with a large parietal cell mass, hypersecretion by antral G cells, and increased vagal tone, resulting in increased or sustained acid secretion in response to meals and increased secretion during the night. The secretagogues that promote gastric acid production include acetylcholine released by the vagus nerve, histamine secreted by enterochromaffin cells, and gastrin released by the G cells of the antrum. Mediators that decrease gastric acid secretion and enhance protective mucin production include prostaglandins.

**Mucosal Defense**

A continuous layer of mucous gel that serves as a diffusion barrier to hydrogen ions and other chemicals covers the gastrointestinal (GI) mucosa. Mucus production and secretion are stimulated by prostaglandin E₂. Underlying the mucous coat, the epithelium forms a second-line barrier, the characteristics of which are determined by the biology of the epithelial cells and their tight junctions. Another important function of epithelial cells is to secrete chemokines when threatened by microbial attack. Secretion of bicarbonate into the mucous coat, which is regulated by prostaglandins, is important for neutralization of hydrogen ions. If mucosal injury occurs, active proliferation and migration of mucosal cells occurs rapidly, driven by epithelial growth factor, transforming growth factor-α, insulin-like growth factor, gastrin, and bombesin, and covers the area of epithelial damage.

**CLINICAL MANIFESTATIONS**

The presenting symptoms of peptic ulcer disease vary with the age of the patient. Hematemesis or melena is reported in up to half of the patients with peptic ulcer disease. School-age children and adolescents more commonly present with epigastric pain and nausea, presentations generally seen in adults. Dyspepsia, epigastric abdominal pain or fullness, is seen in older children. Infants and younger children usually...
inflammation and edema are extensive, acute or chronic gastric outlet obstruction. The classic symptom of peptic ulceration, epigastric pain alleviated by the ingestion of food, is present only in a minority of children. Many pediatric patients present with poorly localized abdominal pain, which may be periumbilical. The vast majority of patients with periumbilical or epigastric pain or discomfort do not have a peptic ulcer, but rather a functional GI disorder, such as irritable bowel syndrome or nonulcer dyspepsia. Patients with peptic ulceration rarely present with acute abdominal pain from perforation or symptoms and signs of pancreatitis from a posterior penetrating ulcer. Occasionally, bright red blood per rectum may be seen if the rate of bleeding is brisk and the intestinal transit time is short. Vomiting can be a sign of gastric outlet obstruction.

The pain is often described as dull or aching, rather than sharp or burning, as in adults. It can last from minutes to hours; patients have frequent exacerbations and remissions lasting from weeks to months. Nocturnal pain waking the child is common in older children. A burning, as in adults. It can last from minutes to hours; patients have frequent exacerbations and remissions lasting from weeks to months. The range of endoscopic findings in children with primary 

**DIAGNOSIS**

Esophagogastroduodenoscopy is the method of choice to establish the diagnosis of peptic ulcer disease. It can be safely performed in all ages by experienced pediatric gastroenterologists. Endoscopy allows the direct visualization of esophagus, stomach, and duodenum, identifying the specific lesions. Biopsy specimens must be obtained from the esophagus, stomach, and duodenum for histologic assessment as well as to screen for the presence of *H. pylori* infection. Endoscopy also provides the opportunity for hemostatic therapy including injection and the use of a heater probe or electrocoagulation if necessary. Fecal enzyme immunoassay tests for *H. pylori* are available and have varying utility in children.

**PRIMARY ULCERS**

*Helicobacter pylori* Gastritis

*H. pylori* is among the most common bacterial infections in humans. *H. pylori* is a Gram-negative, S-shaped rod that produces urease, catalase, and oxidase, which might play a role in the pathogenesis of peptic ulcer disease. The mechanism of acquisition and transmission of *H. pylori* is unclear, although the most likely mode of transmission is fecal–oral or oral–oral. Viable *H. pylori* organisms can be cultured from the stool or vomitus of infected patients. Risk factors such as low socioeconomic status in childhood or affected family members also influence the prevalence. All children infected with *H. pylori* develop histologic chronic active gastritis but are often asymptomatic. In children, *H. pylori* infection can manifest with abdominal pain or vomiting and, less often, refractory iron deficiency anemia or growth retardation. *H. pylori* can be associated, though rarely, with chronic autoimmune thrombocytopenia. Chronic colonization with *H. pylori* can predispose children to a significantly increased risk of developing a duodenal ulcer, gastric cancer such as adenocarcinoma, or mucosa-associated lymphoid tissue lymphomas. The relative risk of gastric carcinoma is 2.3–8.7 times greater in infected adults as compared to uninfected subjects. *H. pylori* is classified by the World Health Organization as a group I carcinogen.

Anemia, idiopathic thrombocytopenic purpura, short stature, and sudden infant death syndrome (SIDS) have also been reported as extragastric manifestations of *H. pylori* infection. In one published study, *H. pylori* infection has been correlated with cases of SIDS, but there is no evidence to suggest that *H. pylori* plays a role in the pathogenesis of SIDS.

The diagnosis of *H. pylori* infection is made histologically by demonstrating the organism in the biopsy specimens (Fig. 335-1). Although serologic assays using validated immunoglobulin G antibody detection may be helpful for screening children for the presence of *H. pylori*, they do not help predict active infection or assess the success of antimicrobial eradication therapy. 13C-urea breath tests and stool antigen tests are also noninvasive methods of detecting *H. pylori* infection. Nonetheless, for children with suspected *H. pylori* infection, an initial upper endoscopy is recommended to evaluate and confirm *H. pylori* disease. The range of endoscopic findings in children with *H. pylori* infection varies from being grossly normal to the presence of nonspecific gastritis with prominent rugal folds, nodularity (Fig. 335-2), or ulcers. Because the antral mucosa appears to be endoscopically normal in a significant number of children with primary *H. pylori* gastritis, gastric biopsies should always be obtained from the body and antrum of the stomach regardless of the endoscopic appearance. If *H. pylori* is identified, even in a child with no symptoms, eradication therapy should be offered (Tables 335-2 and 335-3).

**Idiopathic Ulcers**

*H. pylori*–negative duodenal ulcers in children who have no history of taking NSAIDs represent 15–20% of pediatric duodenal ulcers. These patients do not have nodularity in the gastric antrum or histologic...
The Digestive System

Prostaglandin production increases the risk of mucosal injury. The severe erosive gastropathy produced by NSAIDs can ultimately result in bleeding ulcers or gastric perforations. The location of these ulcers is more common in the stomach than in the duodenum, and usually in the antrum.

**“STRESS” ULCERATION**

Stress ulceration usually occurs within 24 hr of onset of a critical illness in which physiologic stress is present. In many cases, the patients bleed from gastric erosions, rather than ulcers. Approximately 25% of the critically ill children in a pediatric intensive care unit have macroscopic evidence of gastric bleeding. Preterm and term infants in the neonatal intensive care unit can also develop gastric mucosal lesions and can present with upper GI bleeding or perforated ulcers. Although prophylactic measures to prevent stress ulcers in children are not standardized, drugs that inhibit gastric acid production are often used in the treatment of stress ulcerations.

**SECONDARY ULCERS**

**Aspirin and Other Nonsteroidal Antiinflammatory Drugs**

NSAIDs produce mucosal injury by direct local irritation and by inhibiting cyclooxygenase and prostaglandin formation. Prostaglandins enhance mucosal resistance to injury; therefore, a decrease in prostaglandin production increases the risk of mucosal injury. The severe erosive gastropathy produced by NSAIDs can ultimately result in bleeding ulcers or gastric perforations. The location of these ulcers is more common in the stomach than in the duodenum, and usually in the antrum.

Evidence of gastritis. In idiopathic ulcers, acid suppression alone is the preferred effective treatment. Either proton pump inhibitors (PPIs) or H₂ receptor antagonists may be used. Idiopathic ulcers have a high recurrence rate after discontinuing antisecretory therapy. These children should be followed closely, and if symptoms recur, antisecretory therapy should be restarted. In such cases, if the child is older than 1 yr, PPIs are preferred for maintenance therapy, because they have been shown to be superior to H₂ receptor antagonists in preventing recurrent ulcers.

NSAIDs produce mucosal injury by direct local irritation and by inhibiting cyclooxygenase and prostaglandin formation. Prostaglandins enhance mucosal resistance to injury; therefore, a decrease in prostaglandin production increases the risk of mucosal injury. The severe erosive gastropathy produced by NSAIDs can ultimately result in bleeding ulcers or gastric perforations. The location of these ulcers is more common in the stomach than in the duodenum, and usually in the antrum.

**“STRESS” ULCERATION**

Stress ulceration usually occurs within 24 hr of onset of a critical illness in which physiologic stress is present. In many cases, the patients bleed from gastric erosions, rather than ulcers. Approximately 25% of the critically ill children in a pediatric intensive care unit have macroscopic evidence of gastric bleeding. Preterm and term infants in the neonatal intensive care unit can also develop gastric mucosal lesions and can present with upper GI bleeding or perforated ulcers. Although prophylactic measures to prevent stress ulcers in children are not standardized, drugs that inhibit gastric acid production are often used in the treatment of stress ulcerations.
pediatric intensive care unit to reduce the rate of gastric erosions or ulcers.

**TREATMENT**

The management of acute hemorrhage includes serial monitoring of pulse, blood pressure, and hematocrit to insure hemodynamic stability and avoid significant hypovolemia and anemia. Normal saline can be used to resuscitate a patient who has poor intravascular volume status. This can be followed by packed red blood cell transfusions for significant symptomatic anemia. The patient’s blood should be typed and cross matched, and a large-bore catheter should be placed for fluid or blood replacement. A nasogastric tube should be placed to determine if the bleeding has stopped. Significant anemia can occur after fluid resuscitation as a consequence of equilibration or continued blood loss (which can also cause shock). In adults, a conservative threshold for transfusion (<7 g/dL vs 9 g hemoglobin) resulted in improved survival and fewer episodes of rebleeding. Fortunately, most acute peptic ulcer bleeding stops spontaneously.

Patients with suspected peptic ulcer hemorrhage should receive high-dose intravenous PPI therapy, which lowers the risk of rebleeding. Some centers also use octreotide, which lowers splanchnic blood flow and gastric acid production.

Once the patient is hemodynamically stable, endoscopy may be indicated to identify the source of bleeding and treat a potential bleeding site. Methods used for vessel hemostasis include pressure, laser, thermal or electric coagulation; clips; bands; and injections (epinephrine, saline).

Ulcer therapy has 2 goals: ulcer healing and elimination of the primary cause. Other important considerations are relief of symptoms and prevention of complications. The **first-line drugs** for the treatment of gastritis and peptic ulcer disease in children are PPIs and H₂ receptor antagonists (see Table 335-3). PPIs are more potent in ulcer healing. Cytoprotective agents can also be used as adjunct therapy if mucosal lesions are present. Antibiotics in combination with a PPI must be used for the treatment of *H. pylori*-associated ulcers (see Table 335-2). H₁-receptor antagonists (cimetidine, ranitidine, famotidine, nizatidine) competitively inhibit the binding of histamine at the H₂ subtype receptor of the gastric parietal cell. PPIs block the gastric parietal cell H⁺/K⁺–adenosine triphosphatase pump in a dose-dependent fashion, reducing basal and stimulated gastric acid secretion. Currently, 7 PPIs are available in the United States: omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole, dexlansoprazole, and omeprazole/sodium bicarbonate. Apart from the last 2, they are all approved in children and adolescents. They are well tolerated with only minor adverse effects, such as diarrhea (1–4%), headache (1–3%), and nausea (1%). When one considers therapeutic efficacy, the evidence suggests that all PPIs have comparable efficacy in treatment of peptic ulcer disease using standard doses and are superior to H₁-receptor antagonists. PPIs have their greatest effect when given before a meal. Pantoprazole and esomeprazole are the only PPI available in intravenous form in United States. Intravenous PPI should be used in acute upper GI bleeding. In adults, intravenous PPI in acute upper GI bleeding setting decreases the bleeding and need of intervention during endoscopy.

**Treatment of Helicobacter pylori-Related Peptic Ulcer Disease**

In pediatrics, antibiotics and bismuth salts have been used in combination with PPIs to treat *H. pylori* infection (see Table 335-2). Eradication rates in children range from 68–92% when the dual or triple therapy is used for 4–6 wk. The ulcer healing rate ranges from 91–100%. Triple therapy yields a higher cure rate than dual therapy. The optimal regimen for the eradication of *H. pylori* infection in children has yet to be established, but the use of a PPI in combination with clarithromycin and amoxicillin or metronidazole for 2 wk is a well-tolerated and recommended triple therapy (see Table 335-2). Although children younger than 5 yr of age can become reinfected, the most common reason for treatment failure is poor compliance or antibiotic resistance. *H. pylori* has become more resistant to clarithromycin or metronida-...
Bibliography
Bibliography
The term inflammatory bowel disease (IBD) is used to represent 2 distinctive disorders of idiopathic chronic intestinal inflammation: Crohn disease and ulcerative colitis. Their respective etiologies are poorly understood, and both disorders are characterized by unpredictable exacerbations and remissions. The most common time of onset of IBD is during the preadolescent/adolescent era and young adulthood. A bimodal distribution has been shown with an early onset at 10-20 yr of age and a second, smaller peak at 50-80 yr of age. Approximately 25% of patients present before 20 yr of age. IBD may begin as early as the 1st yr of life, and an increased incidence among young children has
been observed since the turn of the century. Children with early-onset IBD are more likely to have colonic involvement. In developed countries, these disorders are the major causes of chronic intestinal inflammation in children beyond the 1st few yr of life. A third, less-common category, indeterminate colitis, represents approximately 10% of pediatric patients.

IBD may be classified according to age at onset; pediatric onset (<17 yr), early onset (<10 yr), very early onset (<6 yr), infant/toddler onset (0-2 yr), and neonatal onset IBD. Children with very early onset (representing ~1% of patients) and those <1 yr of age (0.2%), have a high incidence of monogenic causes of IBD (see Table 336-5) rather than idiopathic and probably polygenetic-environmental causes of IBD.

Genetic and environmental influences are involved in the pathogenesis of IBD. The prevalence of Crohn disease in the United States is much lower for Hispanics and Asians than for whites and blacks. The risk of IBD in family members of an affected person has been reported in the range of 7-30%; a child whose parents both have IBD has a >35% chance of acquiring the disorder. Relatives of a patient with ulcerative colitis have a greater risk of acquiring ulcerative colitis than Crohn disease, whereas relatives of a patient with Crohn disease have a greater risk of acquiring this disorder; the 2 diseases can occur in the same family. The risk of occurrence of IBD among relatives of patients with Crohn disease is somewhat greater than for patients with ulcerative colitis.

The importance of genetic factors in the development of IBD is noted by a higher chance that both twins will be affected if they are monozygotic rather than dizygotic. The concordance rate in twins is higher in Crohn disease (36%) than in ulcerative colitis (16%). Genetic disorders that have been associated with IBD include Turner syndrome, the Hermansky-Pudlak syndrome, glycogen storage disease type Ib, and various immunodeficiency disorders. In 2001, the first IB gene, NOD2, was identified through association mapping. A few months later, the IBD 5 risk haplotype was identified. These early successes were followed by a long period without notable risk factor discovery. Since 2006, the year of the first published genome wide array study on IBD, there has been an exponential growth in the set of validated genetic risk factors for IBD.

A perinuclear antineutrophil cytoplasmic antibody is found in approximately 70% of patients with ulcerative colitis compared with <20% of those with Crohn disease and is believed to represent a marker of genetically controlled immunoregulatory disturbance. Approximately 55% of those with Crohn disease are positive for anti–Saccharomyces cerevisiae antibody. Since the importance of these were first described, multiple other serologic and immune markers of Crohn disease and ulcerative colitis have been recognized.

IBD is caused by dysregulated or inappropriate immune response to environmental factors in a genetically susceptible host. An abnormality in intestinal mucosal immunoregulation may be of primary importance in the pathogenesis of IBD, involving activation of cytokines, triggering a cascade of reactions that results in bowel inflammation. These cytokines are recognized as known or potential targets for IBD therapies.

Multiple environmental factors are recognized to be involved in the pathogenesis of IBD, none more critical than the gut microbiota. The increasing incidence of IBD over time is likely in part attributable to alterations in the microbiome. Evidence includes association between IBD and residence in or immigration to industrialized nations, with a “Western” diet, increased use of antibiotics at a younger age, high rates of vaccination, and less exposure to microbes at a young age. While gut microbes likely play an important role in the pathogenesis of IBD, the exact mechanism needs to be elucidated further. Some environmental factors are disease specific; for example, cigarette smoking is a risk factor for Crohn disease but paradoxically protects against ulcerative colitis.

It is usually possible to distinguish between ulcerative colitis and Crohn disease by the clinical presentation and radiologic, endoscopic, and histopathologic findings (Table 336-1). It is not possible to make a definitive diagnosis in approximately 10% of patients with chronic colitis; this disorder is called indeterminate colitis. Occasionally, a child initially believed to have ulcerative colitis on the basis of clinical findings is subsequently found to have Crohn colitis. This is particularly true for the youngest patients, because Crohn disease in this patient population can more often manifest as exclusively colonic inflammation, mimicking ulcerative colitis. The medical treatments of Crohn disease and ulcerative colitis overlap.

Extraintestinal manifestations occur slightly more commonly with Crohn disease than with ulcerative colitis (Table 336-2). Growth retardation is seen in 15–40% of children with Crohn disease at diagnosis. Decrease in height velocity occurs in nearly 90% of patients. Crohn disease diagnosed in childhood or adolescence. Of the extraintestinal manifestations that occur with IBD, joint, skin, eye, mouth, and hepatobiliary involvement tend to be associated with colitis, whereas Crohn disease. The presence of some manifestations, such as peripheral arthritis, erythema nodosum, and anemia, correlates with activity of the bowel disease. Activity of pyoderma gangrenosum correlates less well with activity of the bowel disease, whereas sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis do not correlate with intestinal disease. Arthritis occurs in 3 patterns: migratory peripheral arthritis involving primarily large joints, ankylosing

Montreal Classification of Extent and Severity of Ulcerative Colitis

Chronic Ulcerative Colitis

Andrew B. Grossman and Robert N. Baldassano

Ulcerative colitis, an idiopathic chronic inflammatory disorder, is localized to the colon and spares the upper gastrointestinal (GI) tract. Disease usually begins in the rectum and extends proximally for a variable distance. When it is localized to the rectum, the disease is ulcerative proctitis, whereas disease involving the entire colon is pancolitis. Approximately 50-80% of pediatric patients have extensive colitis, and adults more commonly have distal disease. Ulcerative proctitis is less likely to be associated with systemic manifestations, although it may be less responsive to treatment than more-diffuse disease. Approximately 30% of children who present with ulcerative proctitis experience proximal spread of the disease. Ulcerative colitis has rarely been noted to present in infancy. Dietary protein intolerance (cow’s milk protein) is a transient disorder; symptoms are directly associated with the intake of the offending antigen.

The incidence of ulcerative colitis has remained relatively constant, in contrast to an increase in Crohn disease, but varies with country of origin. The age-specific incidence rates of pediatric ulcerative colitis in North America is 2 per 100,000 population. The prevalence of ulcerative colitis in northern European countries and the United States varies from 100-200 per 100,000 population. Men are slightly more likely to acquire ulcerative colitis than are women; the reverse is true for Crohn disease.

**CLINICAL MANIFESTATIONS**

Blood, mucus, and pus in the stool as well as diarrhea are the typical presentation of ulcerative colitis. Constipation may be observed in those with proctitis. Symptoms such as tenesmus, urgency, cramping abdominal pain (especially with bowel movements), and nocturnal bowel movements are common. The mode of onset ranges from insidious with gradual progression of symptoms to acute and fulminant (Table 336-3, Fig. 336-1). Fever, severe anemia, hypoalbuminemia, leukocytosis, and more than 5 bloody stools per day for 5 days define fulminant colitis. Chronicity is an important part of the diagnosis; it is difficult to know if a patient has a subacute, transient infectious colitis or ulcerative colitis when a child has had 1-2 wk of symptoms. Symptoms beyond this duration often prove to be secondary to IBD. Anorexia, weight loss, and growth failure may be present, although these complications are more typical of Crohn disease.

**Extraintestinal manifestations** that tend to occur more commonly with ulcerative colitis than with Crohn disease include pyoderma gangrenosum, sclerosing cholangitis, chronic active hepatitis, and ankylosing spondylitis. Iron deficiency can result from chronic blood loss as well as decreased intake. Folate deficiency is unusual but may be accentuated in children treated with sulfasalazine, which interferes with folate absorption. Chronic inflammation and the elaboration of a variety of inflammatory cytokines can interfere with erythropoiesis and result in the anemia of chronic disease. Secondary amenorrhea is common during periods of active disease.

The clinical course of ulcerative colitis is marked by remission and relapse, often without apparent explanation. After treatment of initial symptoms, approximately 5% of children with ulcerative colitis have a prolonged remission (longer than 3 yr). Approximately 25% of children presenting with severe ulcerative colitis require colectomy within 5 yr of diagnosis, compared with only 5% of those presenting with mild disease. It is important to consider the possibility of enteric infection with recurrent symptoms; these infections can mimic a flare-up or actually provoke a recurrence. The use of nonsteroidal antiinflammatory drugs is considered by some to predispose to exacerbation.

It is generally believed that the risk of colon cancer begins to increase after 8-10 yr of disease and can then increase by 0.5-1% per year. The risk is delayed by approximately 10 yr in patients with colitis limited to the descending colon. Proctitis alone is associated with virtually no increase in risk over the general population. Because colon cancer is usually preceded by changes of mucosal dysplasia, it is recommended that patients who have had ulcerative colitis for longer than 10 yr be screened with colonoscopy and biopsies every 1-2 yr. Although this is the current standard of practice, it is not clear if morbidity and mortality are changed by this approach. Two competing concerns about this

---

**Table 336-3**

Montreal Classification of Extent and Severity of Ulcerative Colitis

- **E1 (proctitis):** inflammation limited to the rectum
- **E2 (left-sided; distal):** inflammation limited to the splenic flexure
- **E3 (pancolitis):** inflammation extends to the proximal splenic flexure
- **S0 (remission):** no symptoms
- **S1 (mild):** 4 or less stools per day (with or without blood), absence of systemic symptoms, normal inflammatory markers
- **S2 (moderate):** 4 stools per day, minimum signs of systemic symptoms
- **S3 (severe):** 6 or more bloody stools per day, pulse rate of ≥90 beats per min, temperature ≥37.5°C (99.5°F), hemoglobin concentration <105 g/L, erythrocyte sedimentation rate ≥30 mm/hr

E. extent; S, severity.

- Plan of management remain unresolved. The original studies may have overestimated the risk of colon cancer and, therefore, the need for surveillance has been overemphasized; and screening for dysplasia might not be adequate for preventing colon cancer if some cancers are not preceded by dysplasia.

**DIFFERENTIAL DIAGNOSIS**

The major conditions to exclude are infectious colitis, allergic colitis, and Crohn colitis. Every child with a new diagnosis of ulcerative colitis should have stool cultured for enteric pathogens, stool evaluation for *Clostridium difficile*, ova and parasites, and perhaps serologic studies for amebae (Table 336-4). Cytomegalovirus infection can mimic ulcerative colitis or be associated with an exacerbation of existing disease, usually in immunocompromised patients. The most difficult distinction is from Crohn disease because the colitis of Crohn disease can initially appear identical to that of ulcerative colitis, particularly in younger children. The gross appearance of the colitis or development of small bowel disease eventually leads to the correct diagnosis; this can occur years after the initial presentation.

At the onset, the colitis of hemolytic uremic syndrome may be identical to that of early ulcerative colitis. Ultimately, signs of microangiopathic hemolysis (the presence of schistocytes on blood smear), thrombocytopenia, and subsequent renal failure should confirm the diagnosis of hemolytic-uremic syndrome. Although Henoch-Schönlein purpura can manifest as abdominal pain and bloody stools, it is not usually associated with colitis. Behçet disease can be distinguished by its typical features (see Chapter 161). Other considerations are radiation proctitis, viral colitis in immunocompromised patients, and ischemic colitis (Table 336-5). In infancy, dietary protein intolerance can be confused with ulcerative colitis, although the former is a transient problem that resolves on removal of the offending protein, and ulcerative colitis is extremely rare in this age group. Hirschsprung disease can produce an enterocolitis before or within months after surgical correction; this is unlikely to be confused with ulcerative colitis.

**DIAGNOSIS**

The diagnosis of ulcerative colitis or ulcerative proctitis requires a typical presentation in the absence of an identifiable specific cause (see Tables 336-4 and 336-5) and typical endoscopic and histologic findings (see Tables 336-1 and 336-2). One should be hesitant to make a diagnosis of ulcerative colitis in a child who has experienced symptoms for <2–3 wk until infection has been excluded. When the diagnosis is suspected in a child with subacute symptoms, the physician should make a firm diagnosis only when there is evidence of chronicity on colonic biopsy. Laboratory studies can demonstrate evidence of anemia (either iron deficiency or the anemia of chronic disease) or hypoalbuminemia. Although the sedimentation rate and C-reactive protein are often elevated, they may be normal even with fulminant colitis. An elevated white blood cell count is usually seen only with more-severe colitis. Fecal calprotectin levels are usually elevated and are increasingly recognized to be a more sensitive and specific marker of GI inflammation than typical laboratory parameters. Barium enema is suggestive but not diagnostic of acute (Fig. 336-2) or chronic burned-out disease (Fig. 336-3). The diagnosis of ulcerative colitis must be confirmed by endoscopic and histologic examination of the colon (see Fig. 336-1). Classically, disease starts in the rectum with a gross appearance characterized by erythema, edema, loss of vascular pattern, granularity, and friability. There may be a “cutoff” demarcating the margin between inflammation and normal colon, or the entire colon may be involved. There may
be some variability in the intensity of inflammation even in those areas involved. Flexible sigmoidoscopy can confirm the diagnosis; colonoscopy can evaluate the extent of disease and rule out Crohn colitis. A colonoscopy should not be performed when fulminant colitis is suspected because of the risk of provoking toxic megacolon or causing a perforation during the procedure. The degree of colitis can be evaluated by the gross appearance of the mucosa. One does not generally see discrete ulcers, which would be more suggestive of Crohn colitis. The endoscopic findings of ulcerative colitis result from microulcers, which give the appearance of a diffuse abnormality. With very severe chronic colitis, pseudopolyps may be seen. Biopsy of involved bowel demonstrates evidence of acute and chronic mucosal inflammation.

Typical histologic findings are cryptitis, crypt abscesses, separation of crypts by inflammatory cells, foci of acute inflammatory cells, edema, mucus depletion, and branching of crypts. The last finding is not seen in infectious colitis. Granulomas, fissures, or full-thickness involvement of the bowel wall (usually on surgical rather than endoscopic biopsy) suggests Crohn disease.

Perianal disease, with the exception of mild local irritation or anal fissures associated with diarrhea, should make the clinician think of Crohn disease. Plain radiographs of the abdomen might demonstrate loss of haustral markings in an air-filled colon or marked dilatation with toxic megacolon. With severe colitis, the colon may become dilated; a diameter of >6 cm, determined radiographically, in an adult suggests toxic megacolon. If it is necessary to examine the colon radiologically in a child with severe colitis (to evaluate the extent of involvement or to try to rule out Crohn disease), it is sometimes helpful to perform an upper GI contrast series with small bowel follow-through and then look at delayed films of the colon. A barium enema is contraindicated in the setting of a potential toxic megacolon.

**TREATMENT**

**Medical**

A medical cure for ulcerative colitis is not available; treatment is aimed at controlling symptoms and reducing the risk of recurrence, with a secondary goal of minimizing steroid exposure. The intensity of treatment varies with the severity of the symptoms.

The first drug class to be used with mild or mild-to-moderate colitis is an aminosalicylate. Sulfasalazine is composed of a sulfur moiety linked to the active ingredient 5-aminosalicylate (5-ASA). This linkage prevents the premature absorption of the medication in the upper GI tract, allowing it to reach the colon, where the 2 components are separated by bacterial cleavage. The dose of sulfasalazine is 50-75 mg/kg/24 hr (divided into 2-4 doses). Generally, the dose is not more than 2.4 g/24 hr. Hypersensitivity to the sulfa component is the major side effect of sulfasalazine and occurs in 10-20% of patients. Because of poor tolerance, sulfasalazine is used less commonly than other, better tolerated 5-ASA preparations (mesalamine, 50-100 mg/kg/day; balabalizide 110-175 mg/kg/day). Sulfasalazine and the 5-ASA preparations effectively treat active ulcerative colitis and prevent recurrence. It is recommended that the medication be continued even when the disorder is in remission. These medications might also decrease the lifetime risk of colon cancer.

Approximately 5% of patients have an allergic reaction to 5-ASA, manifesting as rash, fever, and bloody diarrhea, which can be difficult to distinguish from symptoms of a flare of ulcerative colitis. 5-ASA can also be given in enema or suppository form and is especially useful for proctitis. Hydrocortisone enemas are used to treat proctitis as well, but they are probably not as effective. A combination of oral and rectal 5-ASA as well as monotherapy with rectal preparation has been shown to be more effective than just oral 5-ASA for distal colitis. Extended release budesonide may also induce remission in patients with mild to moderate ulcerative colitis.

Probiotics are effective in adults for maintenance of remission for ulcerative colitis, although they do not induce remission during an active flare. The most promising role for probiotics has been to prevent pouchitis, a common complication following colectomy and ileal-pouch anal anastomosis surgery.

Children with moderate to severe pancolitis or colitis that is unresponsive to 5-ASA therapy should be treated with corticosteroids, most commonly, prednisone. The usual starting dose of prednisone is 1-2 mg/kg/24 hr (40-60 mg maximum dose). This medication can be given once daily. With severe colitis, the dose can be divided twice daily and can be given intravenously. Steroids are considered an effective medication for acute flares, but they are not appropriate maintenance medications because of loss of effect and side effects, including growth retardation, adrenal suppression, cataracts, osteopenia, aseptic necrosis of the head of the femur, glucose intolerance, risk of infection, mood disturbance, and cosmetic effects.

For a hospitalized patient with persistence of symptoms despite intravenous steroid treatment for 3-5 days, escalation of therapy or

surgical options should be considered. The validated pediatric ulcerative colitis activity index can be utilized to help determine current disease severity based on clinical factors, and help determine who is more likely to respond to steroids and those who will likely require escalation of therapy (Table 336-6).

With medical management, most children are in remission within 3 mo; however, 5-10% continue to have symptoms unresponsive to treatment beyond 6 mo. Many children with disease requiring frequent corticosteroid therapy are started on immunomodulators such as azathioprine (2.0-2.5 mg/kg/day) or 6-mercaptopurine (1-1.5 mg/kg/day). Uncontrolled data suggest a corticosteroid-sparing effect in many treated patients. This is not an appropriate choice in a steroid nonresponsive patient with acute severe colitis because of longer onset of action. Lymphoproliferative disorders are associated with thiopurine use. Cyclosporine, which is associated with improvement in some children with severe or fulminant colitis, is rarely used owing to its high side-effect profile, its inability to change the natural history of disease, and the increasing use of infliximab, a chimeric monoclonal antibody to tumor necrosis factor (TNF)-α, which is also effective in cases of fulminant colitis. Infliximab is effective for induction and maintenance therapy in adults with moderate to severe disease. TNF blocking agents are associated with an increased risk of infection (particularly tuberculosis) and malignancies (lymphoma, leukemia). Adalimumab is also approved for treatment of moderate to severe ulcerative colitis in adults. Vedolizumab, a humanized monoclonal antibody that inhibits adhesion and migration of leukocytes into the gastrointestinal tract, is approved for the treatment of ulcerative colitis in adults. Tofacitinib, an oral Janus kinase inhibitor, is undergoing trials in adults with active moderate to severe ulcerative colitis.

Surgical

Colectomy is performed for intractable disease, complications of therapy, and fulminant disease that is unresponsive to medical management. No clear benefit of the use of total parenteral nutrition or a

Figure 336-2 Ulcerative colitis. Double-contrast barium enema in a 5 yr old boy who had had intermittent intestinal and extraintestinal symptoms since the age of 3 yr. A, Small ulcerations are distributed uniformly about the colonic circumference and continuously from the rectum to the proximal transverse colon. This pattern of involvement is typical of ulcerative colitis. B, In this coned view of the sigmoid in the same patient, small ulcerations are represented by fine spiculation of the colonic contour in tangent and by fine stippling of the colon surface en face. (From The child with diarrhea. In Hoffman AD, Hilton SW, Edwards DK, editors: Practical pediatric radiology, ed 2, Philadelphia, 1994, WB Saunders, p. 260.)

Figure 336-3 Ulcerative colitis: late changes. This single-contrast barium enema shows the late changes of ulcerative colitis in a 15 yr old girl. The colon is featureless, reduced in caliber, and shortened. Dilation of the terminal ileum (backwash ileitis) is present. (From The child with diarrhea. In Hoffman AD, Hilton SW, Edwards DK, editors: Practical pediatric radiology, ed 2, Philadelphia, 1994, WB Saunders, p 262.)
continuous enteral elemental diet in the treatment of severe ulcerative colitis has been noted. Nevertheless, parenteral nutrition is used if oral intake is insufficient so that the patient will be nutritionally ready for surgery if medical management fails. With any medical treatment for ulcerative colitis, the clinician should always weigh the risk of the medication or therapy against the fact that colitis can be successfully treated surgically.

Surgical treatment for intractable or fulminant colitis is total colectomy. The optimal approach is to combine colectomy with an endorectal pull-through, where a segment of distal rectum is retained and the mucosa is stripped from this region. The distal ileum is pulled down and sutured at the internal anus with a J pouch created from ileum immediately above the rectal cuff. This procedure allows the child to maintain continence. Commonly, a temporary ileostomy is created to protect the delicate anastomosis between the sleeve of the pouch and the rectum. The ileostomy is usually closed within several months, restoring bowel continuity. At that time, stool frequency is often increased but may be improved with loperamide. The major complication of this operation is pouchitis, which is a chronic inflammatory reaction in the pouch, leading to bloody diarrhea, abdominal pain, and, occasionally, low-grade fever. The cause of this complication is unknown, although it is more common when the ileal pouch has been constructed for ulcerative colitis than for other indications (e.g., familial polyposis coli). Pouchitis is seen in 30-40% of patients who had ulcerative colitis. It commonly responds to treatment with oral metronidazole or ciprofloxacin. Probiotics have also been shown to decrease the rate of pouchitis as well as the recurrence of pouchitis following antibiotic therapy.

Support
Psychosocial support is an important part of therapy for this disorder. This may include adequate discussion of the disease manifestations and management between patient and physician, psychologic counseling for the child when necessary, and family support from a social worker or family counselor. Patient support groups have proved helpful for some families. Children with ulcerative colitis should be encouraged to participate fully in age-appropriate activities; however, activity may need to be reduced during periods of disease exacerbation.

**PROGNOSIS**

The course of ulcerative colitis is marked by remissions and exacerbations. Most children with this disorder respond initially to medical management. Many children with mild manifestations continue to respond well to medical management and may stay in remission on a prophylactic 5-ASA preparation for long periods. An occasional child with mild onset, however, experiences intractable symptoms at a later time. Beyond the 1st decade of disease, the risk of development of colon cancer begins to increase rapidly. The risk of colon cancer may be diminished with surveillance colonoscopies beginning after 8-10 yr of disease. Detection of significant dysplasia on biopsy would prompt colectomy.

Bibliography is available at Expert Consult.

**336.2 Crohn Disease (Regional Enteritis, Regional Ileitis, Granulomatous Colitis)**

Andrew B. Grossman and Robert N. Baldassano

Crohn disease, an idiopathic, chronic inflammatory disorder of the bowel, involves any region of the alimentary tract from the mouth to the anus. Although there are many similarities between ulcerative colitis and Crohn disease, there are also major differences in the clinical course and distribution of the disease in the GI tract (see **Table 336-1**). The inflammatory process tends to be eccentric and segmental, often with skip areas (normal regions of bowel between inflamed areas). Although inflammation in ulcerative colitis is limited to the mucosa (except in toxic megacolon), GI involvement in Crohn disease is often transmural.

Compared to adult-onset disease, pediatric Crohn disease is more likely to have extensive anatomic involvement. At initial presentation, more than 50% of patients have disease that involves ileum and colon (ileocolitis), 20% have exclusively colonic disease, and upper GI involvement (esophagus, stomach, duodenum) is seen in up to 30% of children. Isolated small bowel disease is much less common in the pediatric population compared to adults. Isolated colonic disease is common in children younger than 8 yr of age and may be indistinguishable from ulcerative colitis. Anatomic location of disease tends to extend over time in children.

Crohn disease tends to have a bimodal age distribution, with the first peak beginning in the teenage years. The incidence of Crohn disease has been increasing, whereas that of ulcerative colitis has been stable. In the United States, the reported incidence of pediatric Crohn disease is 4.56 per 100,000 and the pediatric prevalence is 43 per 100,000 children.

**CLINICAL MANIFESTATIONS**

Crohn disease can be characterized as inflammatory, strictureing, or penetrating. Patients with small bowel disease are more likely to have an obstructive pattern (most commonly with right lower quadrant pain) characterized by fibrostenosis, and those with colonic disease are more likely to have symptoms resulting from inflammation (diarrhea, bleeding, cramping). Disease phenotypes often change as duration of disease lengthens (inflammatory becomes structuring and/or penetrating) (**Fig. 336-4**). Systemic signs and symptoms are more common in Crohn disease than in ulcerative colitis. Fever, malaise, and easy fatigability are common. Growth failure with delayed bone maturation and delayed sexual development can precede other symptoms by 1 or 2 yr and is at least twice as likely to occur with Crohn disease as with ulcerative colitis. Children can present with growth failure as the only manifestation of Crohn disease. Decreased height velocity occurs in about 88% of prepubertal patients diagnosed with Crohn disease, and this often precedes GI symptoms. Causes of growth failure include inadequate caloric intake, suboptimal absorption or excessive loss of nutrients, the
Bibliography

include bile acid malabsorption with secondary diarrhea and vitamin B₁₂ malabsorption, with possible resultant deficiency. Chronic steatorrhea can lead to oxaluria with secondary renal stones. Increasing calcium intake can actually decrease the risk renal stones secondary to ileal inflammation. The risk of cholelithiasis is also increased secondary to bile acid depletion.

A disorder with this diversity of manifestations can have a major impact on an affected child's lifestyle. Fortunately, the majority of children with Crohn disease are able to continue with their normal activities, having to limit activity only during periods of increased symptoms.

The effects of chronic inflammation on bone metabolism and appetite, and the use of corticosteroids during treatment. Primary or secondary amenorrhea and pubertal delay are common. In contrast to ulcerative colitis, perianal disease is common (tag, fistula, deep fissure, abscess). Gastric or duodenal involvement may be associated with recurrent vomiting and epigastric pain. Partial small bowel obstruction, usually secondary to narrowing of the bowel lumen from inflammation or stricture, can cause symptoms of cramping abdominal pain (especially with meals), borborygmus, and intermittent abdominal distention (Figs. 336-5 and 336-6). Stricture should be suspected if the child notes relief of symptoms in association with a sudden sensation of gurgling of intestinal contents through a localized region of the abdomen.

Penetrating disease is demonstrated by fistula formation. Enterocolonic or enterocolonic fistulas (between segments of bowel) are often asymptomatic but can contribute to malabsorption if they have high output or result in bacterial overgrowth (Fig. 336-7). Entero vesical fistulas (between bowel and urinary bladder) originate from ileum or sigmoid colon and appear as signs of urinary infection, pneumaturia, or fecaluria. Enterovaginal fistulas originate from the rectum, cause feculent vaginal drainage, and are difficult to manage. Enterocutaneous fistulas (between bowel and abdominal skin) often are caused by prior surgical anastomoses with leakage. Intraabdominal abscess may be associated with fever and pain but might have relatively few symptoms. Hepatic or splenic abscess can occur with or without a local fistula. Anorectal abscesses often originate immediately above the anus at the crypts of Morgagni. The patterns of perianal fistulas are complex because of the different tissue planes. Perianal abscess is usually painful, but perianal fistulas tend to produce fewer symptoms than anticipated. Purulent drainage is commonly associated with perianal fistulas. Psoas abscess secondary to intestinal fistula can present as hip pain, decreased hip extension (psoas sign), and fever.

Extraintestinal manifestations occur more commonly with Crohn disease than with ulcerative colitis; those that are especially associated with Crohn disease include oral aphthous ulcers, peripheral arthritis, erythema nodosum, digital clubbing, episcleritis, renal stones (uric acid, oxalate), and gallstones. Any of the extraintestinal disorders described in the section on IBD can occur with Crohn disease (see Table 336-2). The peripheral arthritis is nondeforming. The occurrence of extraintestinal manifestations usually correlates with the presence of colitis.

Extensive involvement of small bowel, especially in association with surgical resection, can lead to short bowel syndrome, which is rare in children. Complications of terminal ileal dysfunction or resection include bile acid malabsorption with secondary diarrhea and vitamin B₁₂ malabsorption, with possible resultant deficiency. Chronic steatorrhea can lead to oxaluria with secondary renal stones. Increasing calcium intake can actually decrease the risk renal stones secondary to ileal inflammation. The risk of cholelithiasis is also increased secondary to bile acid depletion.

A disorder with this diversity of manifestations can have a major impact on an affected child's lifestyle. Fortunately, the majority of children with Crohn disease are able to continue with their normal activities, having to limit activity only during periods of increased symptoms.
more likely to be mistaken for ulcerative colitis than for Crohn disease. Celiac disease and *Giardia* infection have been noted to produce a Crohn-like presentation including diarrhea, weight loss, and protein-losing enteropathy. GI tuberculosis is rare but can mimic Crohn disease. Foreign-body perforation of the bowel (toothpick) can mimic a localized region with Crohn disease. Small bowel lymphoma can mimic Crohn disease but tends to be associated with nodular filling defects of the bowel without ulceration or narrowing of the lumen. Bowel lymphoma is much less common in children than is Crohn disease. Recurrent functional abdominal pain can mimic the pain of small bowel Crohn disease. *Lymphoid nodular hyperplasia* of the termin-inal ileum (a normal finding) may be mistaken for Crohn ileitis. Right lower quadrant pain or mass with fever can be the result of periappendiceal abscess. This entity is occasionally associated with diarrhea as well.

Growth failure may be the only manifestation of Crohn disease; other disorders such as growth hormone deficiency, gluten-sensitive enteropathy (celiac disease), Turner syndrome, or anorexia nervosa must be considered. If arthritis precedes the bowel manifestations, an initial diagnosis of juvenile idiopathic arthritis may be made. Refractory anemia may be the presenting feature and may be mistaken for a primary hematologic disorder. Chronic granulomatous disease of childhood can cause inflammatory changes in the bowel as well as perianal disease. Antral narrowing in this disorder may be mistaken for a stricture secondary to Crohn disease. Other immunodeficiencies or autoinflammatory conditions and monogenetic disorders may present with GI symptoms suggestive of IBD, particularly in very early or infant/toddler onset of disease (see Table 336-5).

**DIAGNOSIS**

Crohn disease can manifest as a variety of symptom combinations. At the onset, symptoms may be subtle (growth retardation, abdominal pain alone); this explains why the diagnosis might not be made until 1 or 2 yr after the start of symptoms. The diagnosis of Crohn disease depends on finding typical clinical features of the disorder (history, physical examination, laboratory studies, and endoscopic or radiologic findings), ruling out specific entities that mimic Crohn disease, and demonstrating chronicity. The history can include any combination of abdominal pain (especially right lower quadrant), diarrhea, vomiting, anorexia, weight loss, growth retardation, and extraintestinal manifestations. Only 25% initially have the triad of diarrhea, weight loss, and abdominal pain. Most do not have diarrhea, and only 25% have GI bleeding.

Children with Crohn disease often appear chronically ill. They commonly have weight loss and growth failure, and they are often

**DIFFERENTIAL DIAGNOSIS**

The most common diagnoses to be distinguished from Crohn disease are the infectious enteropathies (in the case of Crohn disease: acute terminal ileitis, infectious colitis, enteric parasites, and periappendiceal abscess) (see Tables 336-4, 336-5, and 336-7). *Versitus* can cause many of the radiologic and endoscopic findings in the distal small bowel that are seen in Crohn disease. The symptoms of bacterial dysentery are

The small and large bowel and the upper GI tract should be examined by both endoscopic and radiologic studies in the child with suspected Crohn disease. Esophagogastroduodenoscopy and ileocolonoscopy should be performed to properly assess the upper GI tract, terminal ileum, and entire colon. Findings on colonoscopy can include patchy, nonspecific inflammatory changes (erythema, friability, loss of vascular pattern), aphthous ulcers, linear ulcers, nodularity, and strictures. Findings on biopsy may be only nonspecific chronic inflammatory manifestations, or for steroid dependence. More recently, a “top-down” approach has been espoused, particularly in adults after multiple studies demonstrated superior efficacy. With this approach, patients with moderate to severe Crohn disease are treated initially with stronger, disease modifying agents, with the goal of achieving mucosal healing, or deep remission, early in the disease course. This is thought to increase the likelihood of long-term remission while decreasing corticosteroid exposure. The role for this approach in pediatrics is still being determined, but top down treatment is being increasingly utilized.

5-Aminosalicylates

For mild terminal ileal disease or mild Crohn disease of the colon, an initial trial of mesalamine (50-100 mg/kg/day; maximum 3-4 g) may be attempted. Specific pharmaceutical preparations have been formulated to release the active 5-ASA compound throughout the small bowel, in the ileum and colon, or exclusively in the colon. Rectal preparations are used for distal colonic inflammation.
Antibiotics/Probiotics

Antibiotics such as metronidazole (10-20 mg/kg/day) are used for infectious complications, are first-line therapy for perianal disease (although perianal disease usually recurs when antibiotic is discontinued), and they may be effective for treatment of mild to moderate Crohn disease. To date, probiotics have not been shown to be effective in induction or maintenance of remission for pediatric Crohn disease.

Corticosteroids

Corticosteroids are utilized for acute exacerbations of pediatric Crohn disease because they effectively suppress acute inflammation, rapidly relieving symptoms (prednisone, 1-2 mg/kg/day, maximum 40-60 mg). The goal is to taper dosing as soon as the disease becomes quiescent. Clinicians vary in their tapering schedules, and the disease can flare during this process. There is no role for continuing corticosteroids as maintenance therapy because, in addition to their side effects, tolerance develops and steroids do not change disease course or promote healing of mucosa. A special controlled ileal-release formulation of budesonide, a corticosteroid with local antiinflammatory activity on the bowel mucosa and high hepatic first-pass metabolism, is also used for mild to moderate ileal or ileocecal disease (adult dose: 9 mg daily). Ileal-release budesonide appears to be more effective than mesalamine in the treatment of active ileocolonic disease but is less effective than prednisone. Although less effective than traditional corticosteroids, budesonide does cause less steroid-related side effects.

Immunomodulators

Approximately 70% of patients require escalation of medical therapy within in the 1st yr of pediatric Crohn disease diagnosis. Immunomodulators such as azathioprine (2.0-2.5 mg/kg/day) or 6-mercaptopurine (1.0-1.5 mg/kg/day) may be effective in some children who have a poor response to prednisone or who are steroid dependent. Because a beneficial effect of these drugs can be delayed for 3-4 mo after starting therapy, they are not helpful acutely. The early use of these agents can decrease cumulative prednisone dosages over the 1st 1-2 yr of therapy. Genetic variations in an enzyme system responsible for metabolism of these agents (thiopurine S-methyltransferase) can affect response rates and potential toxicity. Lymphoproliferative disorders have developed from thiopurine use in patients with IBD. Other common toxicities include hepatitis, pancreatitis, increased risk of skin cancer, increased risk of infection, and slightly increased risk of lymphoma.

Methotrexate is another immunomodulator that is effective in the treatment of active Crohn disease and has been shown to improve height velocity in the 1st yr of administration. The advantages of this medication include once-weekly dosing by either subcutaneous or oral route (10-15 mg/m², adult dose 25 mg weekly) and a more-rapid onset of action (6-8 wk) than azathioprine or 6-mercaptopurine. Folic acid is usually administered concomitantly to decrease medication side effects. Administration of ondansetron prior to methotrexate has been shown to diminish the risk of the most common side effect of nausea. The most common toxicity is hepatitis. The immunomodulators are effective for the treatment of perianal fistulas.

Biologic Therapy

Therapy with antibodies directed against mediators of inflammation is used for patients with Crohn disease. Infliximab, a chimeric monoclonal antibody to TNF-α, is effective for the induction and maintenance of remission and mucosal healing in chronically active moderate to severe Crohn disease, healing of perianal fistulas, steroid sparing, and preventing postoperative recurrence. Pediatric data additionally support improved growth with the administration of this medication. The onset of action of infliximab is quite rapid and it is initially given as 3 infusions over a 6 wk period (0, 2, and 6 wk), followed by maintenance dosing beginning every 8 wk. The durability of response to infliximab is variable and dose escalation (higher dose and/or decreased interval) is often necessary. Measurement of serum trough infliximab level prior to an infusion can help guide dosing decisions. Side effects include infusion reactions, increased incidence of infections (especially reactivation of latent tuberculosis), increased risk of lymphoma, and the development of autoantibodies. The development of antibodies to infliximab is associated with an increased incidence of infusion reactions and decreased durability of response. Regularly scheduled dosing of infliximab, as opposed to episodic dosing on an as-needed basis, is associated with decreased levels of antibodies to infliximab. A purified protein derivative test for tuberculosis should be done before starting infliximab.

Adalimumab, a subcutaneously administered, fully humanized monoclonal antibody against TNF-α, is effective for the treatment of chronically active moderate to severe Crohn disease in adults and children. After a loading dose, this is typically administered once every 2 wk, although dose escalation is sometimes required with this medication. Vedolizumab, a humanized monoclonal antibody that inhibits adhesion and migration of leukocytes into the gastrointestinal tract, was recently approved for the treatment of Crohn disease in adults. Antibodies against interleukins 12 and 23 antiselective adhesion molecules (ustekinumab), chemokine antagonists, and antagonist to Janus kinase 3 are currently being tested.

Enteral Nutritional Therapy

Exclusive enteral nutritional therapy, whereby all of a patient’s calories are delivered via formula, is an effective primary as well as adjunctive response. The enteral nutritional approach is as rapid in onset of response and as effective as the other treatments. Pediatric studies have suggested similar efficacy to prednisone for improvement in clinical symptoms, but enteral nutritional therapy is superior to steroids for actual healing of mucosa. Because affected patients have poor appetite and these formulas are relatively unpalatable, they are often administered via a nasogastric or gastrostomy infusion, usually overnight. The advantages are that it is relatively free of side effects, avoids the problems associated with corticosteroid therapy, and simultaneously addresses the nutritional rehabilitation. Children can participate in normal daytime activities. A major disadvantage of this approach is that patients are not able to eat a regular diet because they are receiving all of their calories from formula. A novel approach where 80-90% of caloric needs are provided by formula, allowing children to have some food intake, has been successful. For children with growth failure, this approach may be ideal, however.

High-calorie oral supplements, although effective, are often not tolerated because of early satiety or exacerbation of symptoms (abdominal pain, vomiting, or diarrhea). Nonetheless, they should be offered to children whose weight gain is suboptimal even if they are not candidates for exclusive enteral nutritional therapy. The continuous administration of nocturnal nasogastric feedings for chronic malnutrition and growth failure has been effective with a much lower risk of complications than parenteral hyperalimentation.

Surgery

Surgical therapy should be reserved for very specific indications. Recurrence rate after bowel resection is high (>50% by 5 yr); the risk of requiring additional surgery increases with each operation. Potential complications of surgery include development of fistula or stricture, anastomotic leak, postoperative partial small bowel obstruction secondary to adhesions, and short bowel syndrome. Surgery is the treatment of choice for localized disease of small bowel or colon that is unresponsive to medical treatment, bowel perforation, fibrosed strictures with symptomatic partial small bowel obstruction, and intractable bleeding. Intraabdominal or liver abscess sometimes is successfully treated by ultrasonographic or CT-guided catheter drainage and concomitant intravenous antibiotic treatment. Open surgical drainage is necessary if this approach is not successful. Growth retardation was once considered an indication for resection; without other indications, trial of medical and/or nutritional therapy is currently preferred.

Perianal abscess often requires drainage unless it drains spontaneously. In general, perianal fistulas should be managed by a combined medical and surgical approach. Often, the surgeon places a seton through the fistula to keep the tract open and actively draining while
medical therapy is administered, to help prevent the formation of a perianal abscess. A severely symptomatic perianal fistula can require fistulotomy, but this procedure should be considered only if the location allows the sphincter to remain undamaged.

The surgical approach for Crohn disease is to remove as limited a length of bowel as possible. There is no evidence that removing bowel up to margins that are free of histologic disease has a better outcome than removing only grossly involved areas. The latter approach reduces the risk of short bowel syndrome. Laparoscopic approach is increasingly being used, with decreased postoperative recovery time. One approach to symptomatic small bowel stricture has been to perform a strictureplasty rather than resection. The surgeon makes a longitudinal incision across the stricture but then closes the incision with sutures in a transverse fashion. This is ideal for short strictures without active disease. The reoperation rate is no higher with this approach than with resection, whereas bowel length is preserved. Postoperative medical therapy with agents such as mesalamine, metronidazole, azathioprine, and, more recently, infliximab, is often given to decrease the likelihood of postoperative recurrence.

Severe perianal disease can be incapacitating and difficult to treat if unresponsive to medical management. Diversion of fecal stream can allow the area to be less active, but on reconnection of the colon, disease activity usually recurs.

Support
Psychosocial issues for the child with Crohn disease include a sense of being different, concerns about body image, difficulty in not participating fully in age-appropriate activities, and family conflict brought on by the added stress of this disease. Social support is an important component of the management of Crohn disease. Parents are often interested in learning about other children with similar problems, but children may be hesitant to participate. Social support and individual psychologic counseling are important in the adjustment to a difficult problem at an age that by itself often has difficult adjustment issues. Patients who are socially “connected” fare better. Ongoing education about the disease is an important aspect of management because children generally fare better if they understand and anticipate problems. The Crohn and Colitis Foundation of America has local chapters throughout the United States and supports several regional 1-wk camps for children with Crohn disease.

PROGNOSIS
Crohn disease is a chronic disorder that is associated with high morbidity but low mortality. Symptoms tend to recur despite treatment and often without apparent explanation. Weight loss and growth failure can usually be improved with treatment and attention to nutritional needs. Up to 15% of patients with early growth retardation secondary to Crohn disease have a permanent decrease in linear growth. Osteopenia is particularly common in those with chronic poor nutrition and frequent exposure to high doses of corticosteroids. Some of the extraintestinal manifestations can, in themselves, be major causes of morbidity, including sclerosing cholangitis, chronic active hepatitis, pyoderma gangrenosum, and ankylosing spondylitis.

The region of bowel involved and complications of the inflammatory process tend to increase with time and include bowel strictures, fistulas, perianal disease, and intra-abdominal or retroperitoneal abscess. A majority of patients with Crohn disease eventually require surgery for one of its many complications; the rate of reoperation is high. Surgery is unlikely to be curative and should be avoided except for the specific indications noted previously. An earlier, most aggressive medical treatment approach, with the goal of exacting mucosal healing may improve long-term prognosis, and this is an active area of investigation. The risk of colon cancer in patients with long-standing Crohn colitis approaches that associated with ulcerative colitis, and screening colonoscopy after 10 yr of colonic disease is indicated.

Despite these complications, most children with Crohn disease lead active, full lives with intermittent flare-up in symptoms.

Bibliography

Eosinophilic gastroenteritis consists of a group of rare and poorly understood disorders that have in common gastric and small intestine infiltration with eosinophils and peripheral eosinophilia. The esophagus and large intestine may also be involved. Tissue eosinophilic infiltration can be seen in mucosa, muscularis, or serosa. The mucosal form is most common and is diagnosed by identifying large numbers of eosinophils in biopsy specimens of gastric antrum or small bowel. This condition clinically overlaps the dietary protein hypersensitivity disorders of the small bowel and colon. The differential diagnosis also includes celiac disease, chronic granulomatous disease, connective tissue disorders and vasculitides, multiple infections (particularly parasites), hypereosinophilic syndrome, early inflammatory bowel disease, and rarely malignancy. Many patients have allergies to multiple foods, seasonal allergies, atopy, eczema, and asthma. Serum immunoglobulin E is commonly elevated. Peripheral eosinophilia is present in approximately 5-70% of patients with this disorder. Other laboratory abnormalities can include hypoalbuminemia, iron deficiency anemia, and elevated liver enzymes.

The presentation of eosinophilic gastroenteritis is nonspecific. Clinical symptoms often correlate with which layers of the gastrointestinal tract are affected. Mucosal involvement can produce nausea, vomiting, diarrhea, abdominal pain, gastrointestinal bleeding, protein-losing enteropathy, or malabsorption. Involvement of the muscularis can produce obstruction (especially of the pylorus) or intussusception, whereas serosal activity produces abdominal distention and eosinophilic ascites. Presentation in infants can be similar to pyloric stenosis. Laboratory testing often reveals peripheral eosinophilia, elevated serum immunoglobulin E levels, hypoalbuminemia, and anemia.

The disease usually runs a chronic, debilitating course with sporadic severe exacerbations. Although almost always effective for the treatment of isolated eosinophilic esophagitis, elemental diets are not always successful for the treatment of eosinophilic gastroenteritis. Orally administered cromolyn sodium and montelukast are sometimes successful. A majority of patients require treatment with systemic corticosteroids, which are often effective.

Bibliography

All disorders of malabsorption are associated with diminished intestinal absorption of one or more dietary nutrients. Malabsorption can result from a defect in the nutrient digestion in the intestinal lumen or from defective mucosal absorption. Malabsorption disorders can be categorized into generalized mucosal abnormalities usually
resulting in malabsorption of multiple nutrients (Table 338-1) or malabsorption of specific nutrients (carbohydrate, fat, protein, vitamins, minerals, and trace elements) (Table 338-2). Almost all the malabsorption disorders are accompanied by chronic diarrhea which further worsens the malabsorption. (see Chapter 341).

**CLINICAL APPROACH**

The clinical features depend on the extent and type of the malabsorbed nutrient. The common presenting features, especially in toddlers with malabsorption, are diarrhea, abdominal distention, and failure to gain weight, with a fall in growth chart percentiles. Physical findings include abdominal distention, muscle wasting, and the disappearance of the subcutaneous fat, with subsequent loose skinfolds (Fig. 338-1). The nutritional consequences of malabsorption are more dramatic in toddlers because the limited energy reserves and higher proportion of calorie intake being used for weight gain and linear growth. In older children, malnutrition can result in growth retardation, as is commonly seen in children with late diagnosis of celiac disease. If malabsorption is left untreated, linear growth slows, and with prolonged malnutrition, death can follow (see Chapter 46). This extreme outcome is usually restricted to children living in the developing world, where resources to provide enteral and parenteral nutrition support may be limited. Specific findings on examination can guide toward a specific disorder; edema is usually associated with protein-losing enteropathy, digital clubbing with cystic fibrosis and celiac disease, perianal excoriation and gaseous abdominal distention with carbohydrate malabsorption, perianal and circumoral rash with acrodermatitis enteropathica, abnormal hair with Menkes syndrome, and the typical facial features of Johanson-Blizzard syndrome.

Many children with malabsorption disorders have very good appetite as they try to compensate for the fecal protein and energy losses. In exocrine pancreatic insufficiency, fecal losses of up to 40% of ingested protein and energy do not lead to malnutrition, as long as they are compensated by an increased appetite. In conditions associated

| Methotrexate: mucosal injury |
with villous atrophy or inflammation (celiac disease, postinfectious enteropathy), fecal protein and energy losses are usually modest, but associated anorexia and reduced food intake results in malnutrition.

The nutritional assessment is an important part of clinical evaluation in children with malabsorptive disorders (see Chapter 44). Long-term calcium and vitamin D malabsorption can lead to reduced bone mineral density and metabolic bone disease, with increased risk of bone fractures. Vitamin K malabsorption, irrespective of the underlying mechanism (fat malabsorption, mucosal atrophy), can result in coagulopathy. Severe protein-losing enteropathy is often associated with malabsorption syndromes (celiac disease, intestinal lymphangiectasia) and causes hypoalbuminemia and edema. Other nutrient deficiencies include iron malabsorption causing microcytic anemia and anemia, lymphopenia (lymphangiectasia), neutropenia (Shwachman syndrome), and acanthocytosis (abetalipoproteinemia) is useful. If celiac disease is suspected, serum immunoglobulin (Ig) A and tissue transglutaminase (TG2) antibody levels should be determined. Fecal stool elastase-1 can determine exocrine pancreatic insufficiency. A complete blood count including peripheral smear for microcytic anemia, lymphopenia (lymphangiectasia), neutropenia (Shwachman syndrome), and acanthocytosis (abetalipoproteinemia) is useful. If celiac disease is suspected, serum immunoglobulin (Ig) A and tissue transglutaminase (TG2) antibody levels should be determined. Depending on the initial test results, more-specific investigations can be planned.

### INVESTIGATIONS FOR CARBOHYDRATE MALABSORPTION

Measurement of carbohydrate in the stool, using a Clinitest reagent that identifies reducing substances, is a simple screening test. An acidic stool with >2+ reducing substance suggests carbohydrate malabsorption. Sucrose or starch in the stool is not recognized as a reducing sugar until after hydrolysis with hydrochloric acid, which converts them to reducing sugars.

**Breath hydrogen test** is used to identify the specific carbohydrate that is malabsorbed. After an overnight fast, the suspected sugar (lactose, sucrose, fructose, or glucose) is administered as an oral solution (carbohydrate load 1-2 g/kg, maximum 50 g). In malabsorption,
the sugar is not digested or absorbed in the small bowel, passes on to the colon, and is metabolized by the normal bacteria flora. One of the products of this process is hydrogen gas, which is absorbed through the colon mucosa and excreted in the breath. Increased hydrogen concentration in the breath samples suggests carbohydrate malabsorption. A rise in breath hydrogen of 20 ppm above the baseline is considered a positive test. The child should not be on antibiotics at the time of the test, because colonic flora is essential for fermenting the sugar.

Small bowel mucosal biopsies can measure mucosal disaccharidase (lactase, sucrase, maltase, palatinase) concentrations directly. In primary enzyme deficiencies the mucosal enzyme levels are low and small bowel mucosal morphology is normal. Partial or total villous atrophy due to disorders such as celiac disease, or following rotavirus gastroenteritis can result in secondary disaccharidase deficiency and transient lactose intolerance. The disaccharidase levels revert to normal after mucosal healing.

INVESTIGATIONS FOR FAT MALABSORPTION

The presence of fat globules in the stool suggests fat malabsorption. The ability to assimilate fat varies with age; a premature infant can absorb only 65-75% of dietary fat, a full-term infant absorbs almost 90%, and an older child absorbs more than 95% of fat while on a regular diet. Quantitative determination of fat malabsorption requires a 3-day stool collection for evaluation of fat excretion and determination of the coefficient of fat absorption:

\[ \text{Coefficient of fat absorption} = \left( \frac{\text{fat intake} - \text{fecal fat losses}}{\text{fat intake}} \right) \times 100 \]

where fat intake and fat losses are in grams. Because fecal fat balance studies are cumbersome, expensive, and unpleasant to perform, simpler tests are often preferred. Among these stool tests, the acid steatorrhea test is the most reliable. When bile acid deficiency is suspected, the evaluation of bile acid levels in duodenal fluid aspirate may be useful.

Fat malabsorption and exocrine pancreatic insufficiency are usually associated with deficiencies of fat-soluble vitamins A, D, E, and K. Serum concentrations of vitamins A, D, and E can be measured. A prolonged prothrombin time is an indirect test to assess vitamin K deficiency.

INVESTIGATIONS FOR PROTEIN-LOSING ENTEROPATHY

Dietary and endogenous proteins secreted into the bowel are almost completely absorbed; <1 g of protein from these sources passes into the colon. The majority of the stool nitrogen is derived from gut bacterial proteins. Excessive bowel protein loss usually manifests as hypoalbuminemia. Because the most common cause of hypoalbuminemia in children is a renal disorder, urinary protein excretion must be determined. Other potential causes of hypoalbuminemia include liver disease (reduced production) and inadequate protein intake. Very rarely hypoalbuminemia can result from an extensive skin disorder causing protein loss via the skin. Measurement of stool α1-antitrypsin is a useful screening test for protein-losing enteropathy. This serum protein has a molecular weight similar to albumin; however, unlike albumin it is resistant to digestion in the gastrointestinal (GI) tract. Excessive α1-antitrypsin excretion in the stool should prompt further investigations to identify the specific cause of gut or stomach (Menetrier disease) protein loss.

INVESTIGATIONS FOR EXOCRINE PANCREATIC FUNCTION (Fig. 338-2)

Cystic fibrosis is the most common cause of exocrine pancreatic insufficiency in children; therefore, a sweat chloride test must be performed before embarking on invasive tests to investigate possible exocrine pancreatic insufficiency. Many cases of cystic fibrosis are detected by neonatal genetic screening programs; occasional rare mutations are undetected.

Fecal elastase-1 estimation is a sensitive test to assess exocrine pancreatic function in chronic cystic fibrosis and pancreatitis. Elastase-1 is a stable endoprotease unaffected by exogenous pancreatic enzymes. One disadvantage of the fecal elastase-1 test is the lack of full differentiation between primary exocrine pancreatic insufficiency and exocrine pancreatic dysfunction secondary to intestinal villous atrophy. The proximal small bowel is the site for pancreozymin/cholecystokinin production; the latter is the hormone that stimulates enzyme secretion from the exocrine pancreas. Mucosal atrophy can lead to diminished pancreozymin/cholecystokinin secretion and subsequently to exocrine pancreatic insufficiency. Fecal elastase-1 can also give a false-positive result during acute episodes of diarrhea.

Serum trypsinogen concentration can also be used as a screening test for exocrine pancreatic insufficiency. In cystic fibrosis, the levels are greatly elevated early in life, and then they gradually fall, so that by 5-7 yr of age, most patients with cystic fibrosis with pancreatic insufficiency have subnormal levels. Patients with cystic fibrosis and adequate exocrine pancreatic function tend to have normal or elevated levels. In such patients, observing the trend in serial serum trypsinogen estimation may be useful in monitoring exocrine pancreatic function. In Shwachman syndrome, another condition associated with exocrine pancreatic insufficiency, the serum trypsinogen level is low.

Other tests for pancreatic insufficiency (nitroblue tetrazolium–paraaminobenzoic acid test and pancreolauryl test) measure urine or breath concentrations of substances released and absorbed across the mucosal surface following pancreatic digestion. These tests lack specificity and are rarely used in clinical practice.

**Figure 338-2 Algorithm for assessment of exocrine pancreatic function. **If not available, use other test. Perform appropriate imaging studies of the pancreas. **In case of borderline values, consider repeating the test with 3 independent samples. **Consider differential diagnosis (especially consider mucosal villous atrophy and dilution effect of watery stool). GI, gastrointestinal. (Adapted from Walkowiak J, Nouis-Arvanitakis S, Henker J, et al: Indirect pancreatic function tests in children. J Pediatr Gastroenterol Nutr 40:107-114, 2005.)
The gold standard test for exocrine pancreatic function is direct analysis of duodenal aspirate for volume, bicarbonate, trypsin, and lipase upon secretin, and pancreozymin/cholecystokinin stimulation. This involves duodenal intubation (see Chapter 348).

INVESTIGATIONS FOR INTESTINAL MUCOSAL DISORDERS

Establishing a specific diagnosis for malabsorption often requires histologic examination of small bowel mucosal biopsies. These are obtained during endoscopy, which allows multiple biopsies to be performed, because mucosal involvement can be patchy, especially in celiac disease. Periodic acid–Schiff (PAS) staining of mucosal biopsies and electron microscopy are necessary in congenital diarrhea to assess congenital microvillus atrophy. Bowel mucosal lesions can also be segmental in cases of intestinal lymphangiectasia. In these situations, radiographic small bowel series or repeated ultrasonographies can identify a region of thickened bowel responsible for protein loss. During endoscopy, mucosal biopsies can be obtained to measure mucosal disaccharidase activities. Duodenal aspirates can be performed to measure pancreatic enzyme concentration as well as quantitative bacterial cultures. Aspirates to demonstrate other infections and infestations such as Giardia may be useful.

IMAGING PROCEDURES

Plain radiographs and barium contrast studies might suggest a site and cause of intestinal motility disorders. Although flocculations of barium and dilated bowel with thickened mucosal folds have been attributed to diffuse malabsorptive lesions such as celiac disease, these abnormalities are nonspecific. Diffuse fluid-filled bowel loops during sonography also suggest malabsorption.

338.2 Celiac Disease (Gluten-Sensitive Enteropathy)

David Branski, Riccardo Troncone, and Alessio Fasano

ETIOLOGY AND EPIDEMIOLOGY

Celiac disease is an immune-mediated systemic disorder elicited by gluten and related prolamines in genetically susceptible individuals and characterized by the presence of a variable combination of gluten-dependent clinical manifestations, celiac disease–specific antibodies, HLA-DQ2 or DQ8 haplotypes, and enteropathy. Celiac disease–specific antibodies comprise autoantibodies against TG2, including endomysial antibodies (EMA), and antibodies against deamidated forms of gliadin peptides.

Celiac disease is triggered by the ingestion of wheat gluten and related prolamines from rye and barley. In most studies oats proved to be safe; however, a few celiac disease patients have oats prolamine–reactive mucosal T cells that can cause mucosal inflammation.

Celiac disease is a common disorder (1% prevalence of biopsy-proven disease). It is thought to be rare in Central Africa and East Asia. Environmental factors might affect the risk of developing celiac disease or the timing of its presentation. Neither the delayed introduction of gluten, or breastfeeding, or the introduction of small quantities of gluten prevents celiac disease in high-risk patients. Infectious agents have been hypothesized to play a role because frequent rotavirus infections are associated with an increased risk. It is plausible that the contact with gliadin at a time when there is ongoing intestinal inflammation, altered intestinal permeability, and enhanced antigen presentation can increase the risk of developing celiac disease, at least in a subset of persons (Fig. 338–3).

GENETICS AND PATHOGENESIS

A genetic predisposition is suggested by the family aggregation and the concordance in monozygotic twins, which approaches 100%. The strongest association is with human leukocyte antigen (HLA)-DQ2.5 (1 or 2 copies encoded by DQA1 *05 [for the chain] and DQB1*02

Figure 338-3 Causative factors in celiac disease. HLA, human leukocyte antigen. (From Di Sabatino A, Corassa GR: Celiac disease. Lancet 373:1480–1490, 2009.)

genes [for the chain]). Such a DQ molecule has been found to be present in more than 90% of celiac patients. The highly homologous DQ2.2 molecule confers a much lesser risk, while the data available on DQ2-negative celiac disease patients indicate that they almost invariably are HLA-DQ8–positive (DQA1*0301/DQB1*0302). A gene dosage effect has been suggested, and a molecular hypothesis for such a phenomenon has been proposed, based on the impact of the number and quality of the HLA-DQ2 molecules on gluten peptide presentation to T cells. Other non-HLA genes confer susceptibility to celiac disease. Genome-wide association studies have shown risk variants in genes controlling T-cell activation and recruitment, some being shared with type 1 diabetes and other autoimmune diseases. Interestingly, very few polymorphisms associated with celiac disease are in coding regions, as they often are in binding sites for transcription factors, then affecting gene expression.

Celiac disease is a T-cell–mediated chronic inflammatory disorder with an autoimmune component. Altered processing by intraluminal enzymes, changes in intestinal permeability and activation of innate immunity mechanisms precede the activation of the adaptive immune response. Immunodominant epitopes from gliadin are highly resistant to intraluminal and mucosal digestion; incomplete degradation favor gene expression. Some gliadin peptides (p31–43) are able to activate innate immunity, in particular they induce interleukin (IL)-15. The latter, but also type 1 interferons, may alter the tolerogenic phenotype of dendritic cells, resulting in lamina propria T-cell activation by other peptides presented in the context of HLA-DQ2 or HLA-DQ8 molecules. Gliadin-specific T-cell responses are enhanced by the action of TG2; the enzyme converts particular glutamine residues into glutamic acid, which results in higher affinity of these gliadin peptides for HLA-DQ2 or HLA-DQ8. The pattern of cytokines produced following gliadin activation is clearly dominated by interferon-γ (T-helper type 1 skewed); IL-21 is also upregulated. Downstream T-cell activation, a complex remodeling of the mucosa takes place, involving increased levels of metallocproteinases and growth factors, which leads to the classical flat mucosa. A severe impairment of intraepithelial lymphocytes (IELs) homeostasis is present in celiac disease. IL-15 is implicated in the expression of natural killer receptors CD94 and NKG2D, as well as in epithelial expression of stress molecules, thus enhancing cytotoxicity, cell apoptosis, and villous atrophy. The most evident expression of autoimmunity is the presence of serum antibodies to TG2. However, the
mechanisms leading to autoimmunity are largely unknown, as well as their pathogenetic significance. “Potential” celiac disease, in which TG2 antibodies can be detected in situ without any histologic abnormality, shows that the production of antibodies does not necessarily lead to intestinal damage. The finding of IgA deposits on extracellular TG2 in the liver, lymph nodes, and muscles indicates that TG2 is accessible to the gut-derived autoantibodies.

**CLINICAL PRESENTATION AND ASSOCIATED DISORDERS**

Clinical features of celiac disease vary considerably (Table 338-4). Intestinal symptoms are common in children whose disease is diagnosed within the 1st 2 yr of life; failure to thrive, chronic diarrhea, vomiting, abdominal distention, muscle wasting, anorexia, and irritability are present in most cases (see Fig. 338-1). Occasionally there is constipation, rectal prolapse, or intussusception. As the age at presentation of the disease shifts to later in childhood, and with the more liberal use of serologic screening tests, extraintestinal manifestations and associated disorders, without any accompanying digestive symptoms, have increasingly become recognized, affecting almost all organs (Table 338-5).

The most common extraintestinal manifestation of celiac disease is iron-deficiency anemia, unresponsive to iron therapy. Osteoporosis may be present; in contrast to the situation in adults, it can be reversed by a gluten-free diet, with restoration of normal peak bone densitometric values. Other extraintestinal manifestations include short stature, arthritis and arthralgia, epilepsy with bilateral occipital calcifications, peripheral neuropathies, cardiomypathy, isolated hypertransaminasemia, dental enamel hypoplasia, aphthous stomatitis, and alopecia. The mechanisms responsible for the severity and the variety of clinical presentations remain obscure. Nutritional deficiencies or abnormal immune responses have been advocated. Silent celiac disease is being increasingly recognized, mainly in asymptomatic 1st-degree relatives of celiac disease patients investigated during screening studies. However, small bowel biopsy in these people reveals severe mucosal damage consistent with celiac disease. Potential celiac disease is defined when patients have positive celiac disease-specific antibodies, but without documented small bowel damage. It is important to follow these patients because they can develop established celiac disease in the future (Table 338-6).

Some diseases, many with an autoimmune pathogenesis, are found with a higher-than-normal incidence in celiac disease patients. Among these are type 1 diabetes, autoimmune thyroid disease, Addison disease, Sjögren syndrome, autoimmune cholangitis, autoimmune hepatitis, primary biliary cirrhosis. Such associations have been interpreted as a consequence of the sharing of identical HLA haplotypes.

</table>
The relation between celiac disease and other autoimmune diseases is poorly defined; once those diseases are established, they are not influenced by a gluten-free diet. Other associated conditions include selective IgA deficiency and Down, Turner, and Williams syndromes.

Patients with celiac disease show increased long-term mortality, the risk rising with delayed diagnosis and/or poor dietary compliance. Non-Hodgkin lymphoma is the main cause of death. Adult patients can develop complications such as refractory celiac disease, ulcerative jejunoileitis, or enteropathy-associated T-cell lymphoma.

**DIAGNOSIS**

The diagnosis of celiac disease is based on a combination of symptoms, antibodies, HLA, and duodenal histology (Table 338-7). The initial approach to symptomatic patients is to test for anti-TG2 IgA antibodies and in addition for total IgA in serum to exclude IgA deficiency. As an alternative for total IgA in serum direct testing for IgG anti-deamidated forms of gliadin peptides antibodies can be performed. If IgA anti-TG2 antibodies are negative and serum total IgA is normal for age (or IgG anti-deamidated forms of gliadin peptides antibodies are negative), celiac disease is unlikely to be the cause of the symptoms. If anti-TG2 antibody testing is positive the patients should be referred to a pediatric gastroenterologist for further diagnostic workup, which depends on the serum antibody levels. Patients with positive anti-TG2 antibody levels <10 x upper limits of normal should undergo upper endoscopy with multiple biopsies. In patients with positive anti-TG2 antibody levels at or >10 x upper limits of normal, blood should be drawn for HLA and EMA testing. If the patient is positive for EMA antibodies and positive for DQ2 or DQ8 HLA testing, the diagnosis of celiac disease is confirmed, a gluten-free diet is started and the patient is followed for improvement of symptoms and decline of antibodies. In the rare case of negative results for HLA and/or anti-EMA in a child with TG2 antibody titers ≥10 x upper limits of normal, the different possibilities for false-positive and false-negative test results need to be considered. In these circumstances, the diagnostic workup should be extended, including repeated testing and duodenal biopsies. In totally asymptomatic persons belonging to high-risk groups, celiac disease should always be diagnosed using duodenal biopsies. When biopsies are indicated at least 4 fragments should be obtained from the descending part of the duodenum and at least 1 from the duodenal bulb. The diagnosis is confirmed by an antibody decline and preferably a clinical response to a gluten-free diet. Gluten challenge and repetitive biopsies will only be necessary in selected cases in which diagnostic uncertainty remains.

**TREATMENT**

The only treatment for celiac disease is lifelong strict adherence to a gluten-free diet (Fig. 338-4). This requires a wheat-, barley-, and rye-free diet. Despite evidence that oats are safe for most patients with celiac disease, there is concern regarding the possibility of contamination of oats with gluten during harvesting, milling, and shipping. Nevertheless, it seems wise to add oats to the gluten-free diet only when the latter is well established, so that possible adverse reactions can be readily identified. There is a consensus that all celiac disease patients should be treated with a gluten-free diet regardless of the presence of symptoms. However, whereas it is relatively easy to assess the health improvement after treatment of celiac disease in patients with clinical symptoms of the disease, it proves difficult in persons with asymptomatic celiac disease. The nutritional risks, particularly osteopenia, are those mainly feared for subjects who have silent celiac disease and continue on a gluten-containing diet. Little is known about the health risks in untreated patients with minor enteropathy, which may be clinically silent. There are no guidelines concerning the need for a gluten-free diet in subjects with “potential” celiac disease (patients with positive celiac disease–associated serology but without enteropathy).

The Codex Alimentarius Guidelines define gluten-free as <20 ppm, but, although analytical methods for gluten detection have already reached a satisfactory degree of sensitivity, more information is needed on the daily gluten amount that may be tolerated by celiac disease patients. The data available so far seem to suggest that the threshold should be set to <50 mg/day, although individual variability makes it difficult to set a universal threshold.

It is important that an experienced dietitian with specific expertise in celiac disease counseling educates the family and the child about dietary restriction. Compliance with a gluten-free diet can be difficult, especially in adolescents. It is recommended that children with celiac disease be monitored with periodic visits for assessment of symptoms, growth, physical examination, and adherence to the gluten-free diet. Periodic measurements of TG2 antibody levels to document reduction

After biopsy confirmed diagnosis and treatment with gluten-free diet (double arrow), growth improves.](image-url)
in antibody titers can be helpful as indirect evidence of adherence to a gluten-free diet, although they are inaccurate in detecting slight dietary transgressions.

**NONCELIA GLUTEN SENSITIVITY**

Wheat-induced symptoms in patients who do not have celiac disease have been described in 2 groups. IgE-mediated wheat allergy may have overlapping symptoms with celiac disease but more often presents without an enteropathy but with symptoms of atopy (urticaria, angioedema, eczema, asthma, rhinitis) and is diagnosed by the presence of IgE antibodies to wheat (serum specific IgE or skin prick tests). In contrast to celiac disease and noncelia gluten sensitivity, symptoms in IgE-mediated disease occur soon after ingestion of wheat products.

**Gluten sensitivity** has been defined as enteric (abdominal pain, bloating, diarrhea) and systemic (headache, fatigue, muscle aches, rash) after ingesting wheat in the absence of enteropathy or HLA risk factors and autoantibodies. Symptoms are often similar to patients with irritable bowel syndrome and some patients with irritable bowel syndrome respond positively to a gluten-free diet. This is an area of uncertainty in pediatrics because most studies have been performed in adults.

**338.3 Other Malabsorptive Syndromes**

*Philip M. Sherman, David Branski, and Olivier Goulet*

**CONGENITAL INTESTINAL MUCOSAL DEFECTS**

**Microvillus Inclusion Disease (Congenital Microvillus Atrophy)**

Microvillus inclusion disease (MVID) is an autosomal recessive disorder, which manifests at birth with *profuse watery secretory diarrhea*. It is the most severe cause of congenital diarrhea involving the development of intestinal mucosa. Light microscopy of the small bowel mucosa demonstrates diffuse thinning of the mucosa, with hypoplastic villus atrophy and no inflammatory infiltrate. Diagnosis may be easily performed with light microscopy using PAS and CD10 staining, which shows a very thin or absent brush border, together with positive PAS and CD10 intracellular inclusions. Electron microscopy shows enterocytes with absent or sparse microvilli. The apical cytoplasm of the enterocytes contains electron-dense secretory granules; the hallmark is presence of microvilli within involutions of the apical membrane. Polyhydramnios is not a classic presentation of MVID but is increasingly observed according to the progresses in prenatal follow up. Neonates usually present very early onset of severe watery diarrhea (up to 200–330 mL/kg/day) causing dehydration and failure to thrive. Despite parenteral nutrition, diarrhea continues and initial fluid management is difficult. The disease is fatal without long-term parenteral nutrition support. Most children die in infancy or early childhood. To date, no causal treatment exists for MVID. Trials with antiinflammatory drugs, including steroids and antisecretory medications (such as Sandostatin or loperamide), did not significantly change stool volumes over a prolonged period; colostomy and epidermal growth factor have failed as well, but octreotide has shown a partial improvement in 1 patient, supposedly via its ability to reduce intestinal fluids (see Chapter 339).

Intestinal transplantation is the only definitive treatment for this rare disease. Many cases in the same family, frequently in a highly consanguineous union, gave the impression of an autosomal recessive transmission. Mutations of the MYOSB gene coding for a nonconventional motor protein, Myosin Vb, are associated with MVID in a cohort of patients suffering from early-onset MVID. Most early-onset MVID patients display a mutation in MYOSB, but there is a great allelic heterogeneity. These mutations result in a loss of function at the proteic level, with abnormal cell polarity, that would involve MYOSB protein in regulating intracellular protein trafficking as well as in the cytoskeleton organization.

It is likely that in very rare cases a milder phenotype may allow slow weaning from parenteral nutrition, allowing the patient to reach young adulthood and enjoy partial oral feeding.

**Tufting Enteropathy (Congenital Tufting Enteropathy)**

Tufting enteropathy (intestinal epithelial dysplasia) manifests in the 1st few wk of life with *persistent watery diarrhea* and accounts for a small fraction of infants with intractable diarrhea of infancy. The distinctive feature on small intestinal mucosal biopsy is focal epithelial "tufts" (teardrop-shaped groups of closely packed enterocytes with apical rounding of the plasma membrane) involving 80–90% of the epithelial surface. However, the typical pathology does not appear immediately after birth, and in other known enteropathies, tufts are seen on ≤15% of the epithelial surface. One difficulty comes from the mononuclear T cell's infiltration of the lamina propria, which can guide wrongly to a disimmune enteropathy, especially when initially lacking tufts. The increased intestinal permeability caused by cell adhesion defect could be responsible for the inflammatory reaction. Colonic epithelium shows abnormalities that are more difficult to identify. Electron microscopy does not help in establishing the diagnosis.

The pathogenesis of this severe digestive disease is from a disorder of cell–cell and cell–matrix interactions, because there is an abnormal distribution of α5β1-integrin along the crypt–villus axis, increased expression of desmoglein, and ultrastructural changes of desmosomes. Tufting enteropathy is often associated with punctiform keratitis and conjunctival dysplasia resembling typical pictures of tufts. The genetic basis of tufting enteropathy supports this speculation, because mutations in the EPCAM gene, encoding an epithelial cell adhesion molecule protein, have been described. The phenotype associated with mutations of EPCAM is usually an isolated congenital diarrhea without associated extradigestive symptoms, except in some patients with late-onset arthritis. A founder effect at the EPCAM locus in congenital tufting enteropathy (CTE) has been shown in the Arabic Gulf population.

In the *syndromic form* of CTE, diarrhea is associated with one or more of these same anomalies: superficial punctate keratitis, choanal, esophageal or intestinal atresia, anal imperforation, hair dysplasia, skin hyperlaxity, bone abnormalities, hexadactyly, and facial dysmorphism. Anomalies appear isolated for most, except for superficial punctate keratitis and choanal atresia that are consistently found in the population of patients with mutated SPINT2 for conjunctival inflammation (100%) and in 50% of cases for choanal atresia; moreover, these anomalies are never found in the population of patients with EPCAM mutations.

No treatment has been effective, so management requires permanent parenteral nutrition with possible intestinal transplantation (see Chapter 339).

**Enteric Anendocrinosis**

Mutations of the NEUROG3 gene produce generalized mucosal malabsorption, vomiting, diarrhea, failure to thrive, dehydration, and a hyperchloremic metabolic acidosis. Oral alimentation with anything other than water produces diarrhea. Villus-crypt architecture in small bowel biopsies is normal, but staining for neuroendocrine cells (e.g., employing antichromogranin antibodies) demonstrates a complete absence of this secretory cell lineage with preservation of goblet cells and Paneth cells. Treatment is with total parenteral nutrition and small bowel transplantation.

**PROPOTRANE CONVERATASE 1/3 DEFICIENCY**

Chronic watery, neonatal onset diarrhea is described in infants with hyperinsulinism, hypoglycemia, hypogonadism, and hypoadrenalism. Small bowel biopsy reveals a nonspecific enteropathy. A clue to the autosomal recessive condition is subsequent onset of marked obesity with hyperphagia in the toddler years in both affected probands and symptomatic siblings. Elevated serum levels of proinsulin are highly supportive of this underdiagnosed disorder, which is caused by loss-of-function mutations in the PCSK1 gene.
Bibliography

CARBOHYDRATE-DEFICIENT GLYCOPROTEIN SYNDROME AND ENTEROCYTE HEPARAN SULFATE DEFICIENCY

Congenital disorders of glycosylation (also carbohydrate-deficient glycoprotein [CDG]) are genetic disorders of assembly of N-glycans in the cytosol and endoplasmic reticulum, resulting in a variety of manifestations (see Chapter 87.6). The subtypes of CDG I are all associated with protein-losing enteropathy. Diagnosis can be established by isoelectric focusing of serum transferrin, enzyme analysis, and DNA analysis. Oral mannose can provide effective therapy in CDG I Bs, so early identification of children presenting with hypoglycemia, hypothyroidism, and/or thyroid binding globulin deficiency is beneficial.

Congenital enterocyte heparan deficiency is a rare cause of intractable diarrhea with protein-losing enteropathy, which may be an unusual presentation of the CDG syndrome type 1 (also known as Jaeken syndrome) (see Chapter 87.6). Heparan sulfate is a glycosaminoglycan with multiple roles in the intestine, including restriction of charged macromolecules, such as albumin, in the vascular lumen.

SYNDROMIC DIARRHEA

Syndromic diarrhea (SD), also known as phenotypic diarrhea or trichohepatoenteric syndrome is a congenital enteropathy manifesting with early onset of severe diarrhea requiring parenteral nutrition. The estimated prevalence is approximately 1 per 300,000–400,000 live births in Western Europe. Patients are born small for gestational age and present with diarrhea starting in the 1st 6 mo of life (<1 mo of age in most cases). They have an abnormal phenotype, including facial dysmorphism with prominent forehead, broad nose, and hypertelorism and a distinct abnormality of hair, trichorhexis nodosa. Hairs are typically easily removed, and poorly pigmented. Abnormal cutaneous spots including café-au-lait on the lower limbs may be observed. Liver disease affects about half of the patients with extensive fibrosis or cirrhosis. Cardiac abnormalities and colitis have been reported sporadically, as well as 1 case involving polyhydramnios, placental abnormalities, and congenital hemochromatosis. The patients have defective antibody responses despite normal serum immunoglobulin levels and defective antigen-specific skin tests despite positive proliferative responses in vitro. Microscopic analysis shows twisted hair (pili torti), aniso- and poikilotrichosis, and trichorhexis nodosa. Histopathologic analysis shows nonspecific villus atrophy with or without mononuclear cell infiltration of the lamina propria, and without specific histologic abnormalities involving the epithelium. The common association of the disorder with parental consanguinity and/or affected siblings indicates a genetic origin with autosomal recessive transmission. Mutations in the TTC37 gene are the basis of the syndrome. TTC37 encodes a protein known as Thespin, which is in many tissues (vascular endothelium, lymph, pituitary, stalk, lung and intestine), but not expressed in the liver. In patients with SD, with no mutation in TTC37, there are mutations in the SKIV2L gene. This gene encodes a protein of the Ski multiprotein complex that is involved in the control of RNA by the exosome, including the regulation of normal messenger RNA and the degradation of nonfunctional messenger RNA.

Prognosis of this type of intractable diarrhea of infancy is poor, with most patients having died between the ages of 2 and 5 yr, some of them with early-onset liver disease.

AUTOIMMUNE ENTEROPATHY

Symptoms of autoimmune enteropathy usually occur after the 1st 6 mo of life, presenting with chronic diarrhea, protein-losing enteropathy, malabsorption, and failure to thrive. The diagnosis is based on the endoscopic and histologic evaluation of the inflammation mainly of the small bowel but also of the colon. Histologic findings in the small bowel include partial or complete villous atrophy, crypt hyperplasia, and an increase in chronic inflammatory cells in the lamina propria. In contrast to gluten-sensitive enteropathy (celiac disease), there is no increased number in intraepithelial lymphocytes. Immunologic analyses indicate the presence of autoantibodies and, most importantly, of anti-enterocyte antibodies, as well as anti–autoimmune enteropathy-75 kDa. Specific serum antienterocyte antibodies can be identified in 50% or more of patients by indirect immunofluorescent staining of normal small bowel mucosa and kidney. In some patients anti–gdoblet cell antibodies also can be demonstrated.

Extraintestinal autoimmune disorders are usual and include arthritis, membranous glomerulonephritis, insulin-dependent diabetes, thrombocytopenia, autoimmune hepatitis, hypothyroidism, and hemolytic anemia. It is essential to exclude an underlying primary immune deficiency, particularly in boys with other autoimmune features (e.g., diabetes mellitus), because a proportion has underlying immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome (see Chapter 126.5). Different phenotypes of IPEX syndrome patients, as well as IPEX-like forms of autoimmune enteropathy that are FOXP3-independent are described involving girls as well with or without extraintestinal autoimmune disorders. Contrary to classical IPEX, the cause of IPEX-like or type 2 autoimmune enteropathy is only partially elucidated on a molecular basis. However, in patients who do not show genetic defects in FOXP3 or CD25, abnormal functions of CD4+CD25 high regulatory T cells should be documented. Autoimmune enteropathy is reported in cases of Schimke immunoosseous dysplasia.

Bile acid malabsorption

In primary bile acid malabsorption, mutation of the ileal sodium–bile acid cotransporter gene, SLC10A2, results in congenital diarrhea, steatorrhea, interruption of enterohepatic circulation of bile acids, and reduced plasma cholesterol levels. Bile acids are normally synthesized from cholesterol in the liver and secreted into the small intestine, where they facilitate absorption of fat, fat-soluble vitamins, and cholesterol. Bile acids are reabsorbed in the distal ileum, return to the liver via the portal venous circulation, and reenter into bile. Normally, the enterohepatic circulation of bile acids is an extremely efficient process; only 10% of the intestinal bile acids escape reabsorption and are eliminated in feces. Bile acid secretion is largely autoregulated, but there is only a limited capacity to increase bile acid secretion. Reduction in the bile acid pool from bile acid malabsorption causes steatorrhea, which requires restriction of dietary fat. Unabsorbed bile acids stimulate cholesterogenesis in the colon, resulting in diarrhea, which responds to cholestyramine, an anion-binding resin. Secondary bile acid malabsorption can result from ileal disease, such as in Crohn disease, and following an ileal resection.

Chronic neonatal-onset diarrhea has also been described in autosomal recessive cerebrotendinous xanthomatosis, which is caused by an inborn error of bile acid synthesis resulting from 27-hydroxylase deficiency. These children also present with juvenile-onset cata racts and developmental delay. Neonatal cholestasis has also been described as a presenting feature. Tendon xanthomas develop in the second and third decades of life. The diagnosis is important to establish, because treatment is effective when employing oral chenodeoxycholic acid.

INTESTINAL LYMPHANGIECTASIA

Obstruction of the lymphatic drainage of the intestine can be caused by either congenital defects in lymphatic duct formation or by secondary causes (Table 338-8). The congenital form is often associated with lymphatic abnormalities elsewhere in the body, as occur with Turner, Noonan, and Klippel-Trenaunay-Weber syndromes. Causes of secondary lymphangiectasia include constrictive pericarditis, heart failure, retroperitoneal fibrosis, abdominal tuberculosis, and retroperitoneal malignancies. Lymph rich in proteins, lipids, and lymphocytes leak
The diagnosis is suggested by the typical findings in association with an elevated fecal α₁-antitrypsin clearance. Radiologic findings of uniform, symmetric thickening of mucosal folds throughout the small intestine are characteristic but nonspecific. Small bowel mucosal biopsy can show dilated lacteals with distortion of villi and no inflammatory infiltrate. A patchy distribution and deeper mucosal involvement on occasion causes false-negative results on small bowel histology. Video capsule endoscopy may reveal similar lesions (Figs. 338-5 and 338-6). Treatment of lymphangiectasia includes restricting the amount of long-chain fat ingested and administering a formula containing protein and medium-chain triglycerides (MCTs). Supplementing a low-fat diet with MCT oil in cooking is used in the management of older children with lymphangiectasia. Rarely, parenteral nutrition is required. If only a portion of the intestine is involved, surgical resection may be considered.

ABETALIPOPROTEINEMIA

Abetalipoproteinemia is a rare autosomal recessive disorder of lipoprotein metabolism (Bassen-Kornzweig syndrome) (see Chapter 86). It is associated with severe fat malabsorption from birth. Children fail to thrive during the 1st yr of life, with stools that are pale, foul smelling, and bulky. The abdomen is distended and deep tendon reflexes are absent as a result of peripheral neuropathy, which is secondary to vitamin E (fat-soluble vitamin) deficiency. Intellectual development tends to be slow. After 10 yr of age, intestinal symptoms are less severe, ataxia develops, and there is a loss of position and vibration sensation into the bowel lumen, resulting in protein-losing enteropathy, steatorrhea, and lymphocyte depletion. Hypoalbuminemia, hypogammaglobulinemia, edema, lymphopenia, malabsorption of fat and fat-soluble vitamins, and chylous ascites often occur. Intestinal lymphangiectasia can also manifest as ascites, peripheral edema and a low serum albumin.

The diagnosis is suggested by the presence of acanthocytes in the peripheral blood smear and extremely low plasma levels of cholesterol (<50 mg/dL); triglycerides are also very low (<20 mg/dL). Chylomicrons and very-low-density lipoproteins are not detectable, and the low-density lipoprotein fraction is virtually absent from the circulation. Marked triglyceride accumulation in villus enterocytes occurs in the duodenal mucosa. Steatorrhea occurs in younger patients, but other processes of nutrient assimilation are intact. Rickets may be an unusual initial
manifestation of abetalipoproteinemia and hypobetalipoproteinemia. Rickets is caused by steatorrhea-induced calcium losses and vitamin D deficiency. Patients have mutations of the microsomal triglyceride transfer protein gene, resulting in absence of microsomal triglyceride transfer protein function in the small bowel. This protein is required for normal assembly and secretion of very low density lipoproteins and chylomicrons.

Specific treatment is not available. Large supplements of the fat-soluble vitamins A, D, E, and K should be given. Vitamin E (100-200 mg/kg/24 hr) appears to arrest neurologic and retinal degeneration. Limiting long-chain fat intake can alleviate intestinal symptoms; MCTs can be used to supplement fat intake.

HOMOZYGOUS HYPOBETALIPOPROTEINEMIA

Homozygous hypobetalipoproteinemia (see Chapter 86) is transmitted as an autosomal dominant trait. The homozygous form is indistinguishable from abetalipoproteinemia. The parents of these patients, as heterozygotes, have reduced plasma low-density lipoprotein and apoprotein-β concentrations, whereas the parents of patients with abetalipoproteinemia have normal levels. On transmission electron microscopy of small bowel biopsies, the size of lipid vacuoles in enterocytes differentiates between abetalipoproteinemia and hypobetalipoproteinemia: many small vacuoles are present in hypobetalipoproteinemia, and larger vacuoles are seen in abetalipoproteinemia.

CHYLOMICRON RETENTION DISEASE (ANDERSON DISEASE)

In chylomicron retention disease, a rare recessive disorder, there is a defect in chylomicron exocytosis from enterocytes. Sar1 guanosine triphosphate promotes the formation of endoplasmic reticulum to Golgi transport carriers, and Sar1b is defective in Anderson disease. These patients have severe intestinal symptoms with steatorrhea, chronic diarrhea, and failure to thrive. Acanthocytosis is rare and neurologic manifestations are less severe than those observed in abetalipoproteinemia. Plasma cholesterol levels are moderately reduced (<75 mg/dL) and fasting triglycerides are normal, but the fat-soluble vitamins, particularly A and E, are very low. Treatment is early aggressive therapy with fat-soluble vitamins and modification of dietary fat intake, as in the treatment of abetalipoproteinemia.

WOLMAN DISEASE

Wolman disease is a rare, lethal lipid storage disease that leads to lipid accumulation in multiple organs, including the small intestine. In addition to vomiting, severe diarrhea, and hepatosplenomegaly, patients have steatorrhea as a result of lymphatic obstruction. Deficiency of lysosomal acid lipase is the underlying cause of disease (see Chapter 80). Successful long-term bone marrow engraftment results in normalization of peripheral blood leukocyte lysosomal enzyme acid lipase activity, with subsequent resolution of diarrhea and the restoration of developmental milestones.

DGAT1 MUTATION

Two siblings in one family with severe protracted diarrhea starting at 3 days of age had loss-of-function homozygous splice mutations in the diacylglycerol acyltransferase (DGAT1) gene that catalyzes the final step in the synthesis of triglycerides.

Bibliography is available at Expert Consult.

338.4 Intestinal Infections and Infestations Associated with Malabsorption

Raanan Shamir and David Branski

Malabsorption is a rare consequence of primary intestinal infection and infestation in immunocompetent children. Malabsorption is mainly seen after infection with Campylobacter, Shigella, Salmonella, Giardia, cryptosporidium, coccidioidosis, and rotavirus. These infec-tious causes of malabsorption are more common in immunocompromised children.

POSTINFECTIOUS DIARRHEA

In infants and very young toddlers chronic diarrhea can appear following infectious enteritis, regardless of the nature of the pathogen. The pathogenesis of the diarrhea is not always clear and may be related to secondary lactase deficiency, food protein allergy, antibiotic-associated colitis (including pseudomembranous colitis caused by Clostridium difficile toxin), or a combination of these.

Treatment is supportive and may include a lactose-free diet in the presence of secondary lactase deficiency; infants might require a semielemental diet. The beneficial effect of specific probiotic products should await well-controlled clinical trials.

BACTERIAL OVERGROWTH

Bacteria are normally present in large numbers in the colon (10^{11}-10^{13} colony-forming units [CFU]/g of feces) and have a symbiotic relationship with the host, providing nutrients and protecting the host from pathogenic organisms. Bacteria are usually present only in a small number in the stomach and small bowel, except for bacteria in the colon, which are harmful. Gastric acid pH prevents the ingested organisms from colonizing the small bowel. Small bowel motility and the migrating motor complex cleanse the small bowel between meals and at night; the ileocecal valve prevents colonic bacteria from refluxing into the ileum.

Specific treatment of bacterial overgrowth focuses on correction of underfeeding. Limiting long-chain fat intake can alleviate intestinal symptoms; MCTs can be used to supplement fat intake.

Rickets is caused by steatorrhea-induced calcium losses and vitamin D deficiency. Patients have mutations of the microsomal triglyceride transfer protein gene, resulting in absence of microsomal triglyceride transfer protein function in the small bowel. This protein is required for normal assembly and secretion of very low density lipoproteins and chylomicrons.

Specific treatment is not available. Large supplements of the fat-soluble vitamins A, D, E, and K should be given. Vitamin E (100-200 mg/kg/24 hr) appears to arrest neurologic and retinal degeneration. Limiting long-chain fat intake can alleviate intestinal symptoms; MCTs can be used to supplement fat intake.
Bibliography

because it follows outbreaks of acute diarrheal disease and improves with antibiotic therapy, an infectious etiology is suspected. The incidence is decreasing worldwide, possibly due to common use of antibiotics for gastroenteritis in developing countries. Yet, in 2011, tropical sprue was still the leading cause of malabsorption in a referral center in south India. Clinical symptoms include fever and malaise followed by watery diarrhea. After about a week the acute features subside, and anorexia, intermittent diarrhea, and chronic malabsorption result in severe malnutrition characterized by glossitis, stomatitis, cheilitis, night blindness, hyperpigmentation, and edema reflecting the various nutrient deficiencies. Muscle wasting is often marked, and the abdomen is often distended. Megaloblastic anemia results from folate and vitamin $B_12$ deficiencies.

Diagnosis is made by small bowel biopsy, which shows villous flattening, crypt hyperplasia, and a chronic inflammatory cell infiltrate of the lamina propria with adjacent lipid accumulation in the surface epithelium.

**Treatment** requires nutritional supplementation, including supplementation of folate and vitamin $B_12$. To prevent recurrence, 6 mo of therapy with oral folic acid (5 mg) and tetracycline or sulfonamides is recommended. Relapses occur in 10-20% of patients who continue to reside in an endemic tropical region; additional courses of antibiotics may be necessary.

**WHipple DISEase**

Whipple disease is a chronic systemic infectious disorder. It is a rare disease, especially in childhood. The disease is caused by an infectious agent, *Tropheryma whippelii*, which can be cultured from a lymph node in the involved tissue.

The most common symptoms in Whipple disease are diarrhea, abdominal pain, weight loss, and joint pains. Malabsorption, lymphadenopathy, skin hyperpigmentation, and neurologic changes are also common. Neurologic manifestations and malabsorption are also common.

Involvement of other organs such as eyes, heart, and kidneys has been reported.

Diagnosis requires a high index of suspicion and is made upon demonstration of PAS-positive macrophage inclusions in the biopsy material, usually a duodenal biopsy. Positive identification using polymerase chain reaction for *T. whippelii confirms the diagnosis. It should not be done on stool specimens, because false-positive results were reported in healthy individuals.*

**Treatment** requires antibiotics such as cotrimoxazole for 1-2 yr. A 2-wk course of intravenous ceftriaxone or meropenem, followed by cotrimoxazole for 1 yr, is recommended.

### 338.5 Immunodeficiency Disorders

_Ernest G. Seidman and David Branski_

Malabsorption can occur with congenital immunodeficiency disorders, and chronic diarrhea with failure to thrive is often the mode of presentation. Defects of humoral and or cellular immunity may be involved, including selective IgA deficiency, agammaglobulinemia, common variable immunodeficiency disease (CVID), severe combined immunodeficiency, Wiskott–Aldrich syndrome, or chronic granulomatous disease. Although most patients with selective IgA deficiency are asymptomatic, malabsorption caused by giardiasis or nonspecific enteropathy with bacterial overgrowth can occur. Malabsorption syndrome or chronic noninfectious diarrhea has been reported in 60% of children with CVID, most often in the subgroup with low memory B cell counts. Malabsorption has also been reported in approximately 10% of patients with late-onset CVID, often secondary to giardiasis. Celiac disease is more common in patients with IgA deficiency and CVID. Paradoxically, it is more difficult to exclude the diagnosis of celiac disease because of the lack of reliability of IgA- and IgG-based serologic tests. Malabsorption as a result of chronic rotavirus, giardiasis, bacterial overgrowth, and protein-losing enteropathy are well-recognized complications of X-linked agammaglobulinemia. Malabsorption associated with immunodeficiency is exacerbated by villus atrophy and secondary disaccharidase deficiency. In chronic granulomatous disease, phagocytic function is impaired and granulomas develop throughout the GI tract, mimicking Crohn disease. In addition to failure to thrive, it is important to consider that malabsorption associated with immunodeficiency is often complicated by micronutrient deficiencies, including vitamins A, E, and $B_12$, and calcium, zinc, and iron.

Overall, immunodeficiencies such as hypogammaglobulinemia in the pediatric age group are more often secondary to other conditions such as cancer and chemotherapy, chronic infections, malabsorption, nephrotic syndrome, or cardiac disease. Malnutrition, diarrhea, and failure to thrive are common in untreated children with HIV infection. The risk of GI infection is related to the depression of the CD4 count. Opportunistic infections include *Cryptosporidium parvum*, cytomegalovirus, *Mycobacterium avium-intracellulare*, *Isospora belli*, *Enterocytozoon bieneusi*, *Candida albicans*, astrovirus, calicivirus, adenovirus, and the usual bacterial enteropathogens. In these patients, *Cryptosporidium* can cause a chronic secretory diarrhea.

**Cancer chemotherapy** can damage the bowel mucosa, leading to secondary malabsorption of disaccharides such as lactose. After bone marrow transplantation, mucosal damage from graft-versus-host disease can cause diarrhea and malabsorption. Small bowel biopsies show nonspecific villus atrophy, mixed inflammatory cell infiltrates, and increased apoptosis. Cancer chemotherapy and bone marrow transplantation are associated with pancreatic damage leading to exocrine pancreatic insufficiency.

### 338.6 Immunoproliferative Small Intestinal Disease

_Ernest G. Seidman and David Branski_

Malignant lymphomas of the small intestine are categorized into 3 subtypes: Burkitt lymphoma, non-Hodgkin lymphomas, and Mediterranean lymphoma. Burkitt lymphoma, the most common form in children, characteristically involves the terminal ileum with extensive abdominal involvement. The relatively uncommon “Western” type of non-Hodgkin lymphomas (usually large B-cell type), can involve various parts of the small intestine. **Mediterranean lymphoma** predominantly involves the proximal small intestine. The World Health Organization recommended the term immunoproliferative small intestinal disease (IPSID) for the syndrome associated with Mediterranean lymphoma, because in its early stages it does not appear to be a truly malignant lymphoma. Many of the patients with “secretory” IPSID syndrome have variable levels of abnormal immunoglobulin in serum or other body fluids, identified as truncated $\alpha$ heavy chain. The World Health Organization classification lists IPSID with heavy chain diseases as a special variant of extranodal marginal zone B-cell small intestinal mucosa-associated lymphoid tissue lymphoma.

IPSID occurs most often in the proximal small intestine in older children and young adults in the Mediterranean basin, Middle East, Asia, and Africa. Poverty and frequent episodes of gastroenteritis during infancy are antecedent risk factors. The initial clinical presentation is intermittent diarrhea and abdominal pain. Later, chronic diarrhea with malabsorption (60-80%), protein-losing enteropathy, weight loss, digital clubbing, and growth failure ensue. Intestinal obstruction, abdominal masses, and ascites are common in advanced stages.

In contrast to primary nonimmunoproliferative small intestinal lymphomas, in which the pathology in the intestine is usually focal, involving specific segments of the intestine and leaving the segments between the involved areas free of disease, the pathology in IPSID is diffuse, with a mucosal cellular infiltrate involving large segments of
Bibliography

Bibliography
the intestine and sometimes the entire length of the intestine, thus producing malabsorption. Molecular and immunohistochemical studies demonstrated an association with *Campylobacter jejuni* infection. The differential diagnosis includes chronic enteric infections (parasites, tropical sprue), celiac disease, and other lymphomas. Radiologic findings include multiple filling defects, ulcerations, strictures, and enlarged mesenteric lymph nodes on CT scan.

The diagnosis is usually established by endoscopic biopsies and/or laparotomy. Upper endoscopy shows thickening, erythema, and nodularity of the mucosal folds in the duodenum and proximal jejunum. As the disease progresses, tumors usually appear in the proximal small intestine and rarely in the stomach. The diagnosis requires multiple duodenal and jejunal mucosal biopsies showing dense mucosal infiltrates, consisting of centrocyte-like and plasma cells. Progression to higher-grade large-cell lymphoplasmacytic and immunoblastic lymphoma is characterized by increased plasmocytic atypia with formation of aggregates and later sheets of dystrophic plasma cells and immunoblasts invading the submucosa and muscularis propria. A serum marker of IgA, a heavy-chain paraprotein, is present in most cases.

**Treatment** of early-stage IPSID with antibiotics results in complete remission in 30-70% of cases. However, the majority of untreated IPSID cases progress to lymphoplasmacytic and immunoblastic lymphoma invading the intestinal wall and mesenteric lymph nodes and can metastasize to distant organs, requiring chemotherapy.

### 338.7 Short Bowel Syndrome

_Jon A. Vanderhoof and David Branski_

Short bowel syndrome results from congenital malformations or resection of the small bowel. Table 338-9 lists the causes of short bowel syndrome. Loss of >50% of the small bowel, with or without a portion of the large intestine, can result in symptoms of generalized malabsorption disorder or in specific nutrient deficiencies, depending on the region of the bowel resected. At birth, the length of small bowel is 200-250 cm; by adulthood, it grows to 300-800 cm. Bowel resection in an infant has a better prognosis than in an adult because of the potential for intestinal growth. An infant with as little as 15 cm of bowel with an ileocecal valve, or 20 cm without, has the potential to survive and be eventually weaned from total parenteral nutrition.

In addition to the length of the bowel, the anatomic location of the resection is also important. The jejunum has more circular folds and longer villi. The proximal 100-200 cm of jejunum is the main site for carbohydrate, protein, iron, and water-soluble vitamin absorption, whereas fat absorption occurs over a longer length of the small bowel. Depending on the region of the bowel resected, specific nutrient malabsorption can result. Vitamin B<sub>12</sub> and bile salts are only absorbed in the distal ileum (Fig. 338-7). Jejunal resections are generally tolerated better than ileal resections because the ileum can adapt to absorb nutrients and fluids. Net sodium and water absorption is relatively much higher in the ileum. Ileal resection has a profound effect on fluid and electrolyte absorption due to malabsorption of sodium and water by the remaining ileum; ileal malabsorption of bile salts stimulates increased colonic secretion of fluid and electrolytes.

TREATMENT

After bowel resection, treatment of short bowel syndrome is initially focused on repletion of the massive fluid and electrolyte losses while the bowel initially accommodates to absorb these losses. Nutritional support is often provided via parenteral nutrition. A central venous catheter should be inserted to provide parenteral fluid and nutrition support. The ostomy or stool output should be measured and fluid and electrolyte losses adequately replaced. Measurement of urinary Na+ to assess body Na+ stores is useful to prevent Na+ depletion. Maintaining urinary Na+ higher than K+ ensures that Na+ intake is adequate. Use of oral glucose electrolyte solutions improves intestinal sodium absorption, particularly in patients without a colon.

After the initial few weeks following resection, fluid and electrolyte losses stabilize, and the focus of therapy shifts to bowel rehabilitation with the gradual reintroduction of enteral feeds. Continuous small-volume trophic enteral feeding should be initiated with a high-calorie formula. MCT-enriched formula or mother’s milk to stimulate gut hormones and promote mucosal growth. Enteral feeding also increases pancreatic flow and reduces parenteral nutrition-induced hepatotoxicity. As soon as possible, the infant should be given a small amount of water and then formula or mother’s milk by mouth to maintain an interest in oral feeding and minimize or avoid the development of oral aversion. As intestinal adaptation occurs, enteral feeding increases and parenteral supplementation decreases. The bowel mucosa proliferates and bowel lengths with growth.

Approximately 50% of patients with short bowel syndrome achieve enteral autonomy within 5 yr of bowel resection. Many have initial successes but then require intermittent periods of parenteral nutrition. Enteral autonomy often requires years to achieve.

Patients may require repeat surgeries for obstruction or bowel lengthening procedures (longitudinal lengthening, serial transverse enteroplasties, or both).

After achieving the maximal increase in bowel absorptive capacity, management of specific micronutrient and vitamin deficiencies and treatment of transient problems such as postinfectious mucosal malabsorption are required. GI infections such as rotavirus or small bowel bacterial overgrowth can cause setbacks in the progression to full enteral feeding in patients with marginal absorptive function. A marked increase in stool output or evidence of carbohydrate malabsorption (stool pH <5.5 and positive test for reducing substances) contraindicates further increases in enteral feeds. Slow advancement of continuous enteral feeding rates continues until all nutrients are provided enterally. Then the feeds can be altered to include increased oral or bolus feeding volumes.

In patients with large stool output, the addition of soluble fiber and antidiarrheal agents such as loperamide and anticholinergics can be beneficial, although these drugs can increase the risk of bacterial overgrowth. Cholestyramine can be beneficial for patients with distal ileal resection, but its potential depletion of the bile acid pool can increase steatorrhea. Bacterial overgrowth is common in infants with a short bowel and can delay progression of enteral feedings. Empirical treatment with metronidazole or other antibiotics (nitazoxanide, rifaxidine) is often useful. Diets high in fat and lower in carbohydrate may be helpful in reducing bacterial overgrowth as well as enhancing adaptation.

COMPLICATIONS

Long-term complications of short bowel syndrome include those of parenteral nutrition: central catheter infection, thrombosis, hepatic cholestasis and cirrhosis, and gallstones. Appropriate care of the central line to prevent infection and catheter-related thrombosis is extremely important. Sepsis is a leading cause of death, can occur any time after treatment is initiated (months to years later), and is most often bacterial (single organism more common than polymicrobial), although fungal infection may be noted in 20–25% of septic episodes.

Some patients need long-term parenteral nutritional support, and lack of central line access is potentially life-threatening; inappropriate removal or changes of central lines in the neonatal period should be avoided. Other complications of terminal ileal resection include vitamin B₁₂ deficiency, which might not appear until 1–2 yr after parenteral nutrition is withdrawn. Long-term monitoring for deficiencies of vitamin B₁₂, folate, iron, fat-soluble vitamins, and trace minerals such as zinc and copper is important. Renal stones can occur as a result of hyperoxaluria secondary to steatorrhea (calcium binds to the excess fat and not to oxalate, so more oxalate is reabsorbed and excreted in the urine). Venous thrombosis and vitamin deficiency have been associated with hyperhomocystinemia in short bowel syndrome. Bloody diarrhea secondary to patchy, mild colitis can develop during the progression of enteral feedings. The pathogenesis of this “feeding colitis” is unknown, but it is usually benign and can improve with a hypoallergenic diet or treatment with mesalamine.

In patients who are unable to achieve full enteral feeding after several years of nutritional rehabilitation, surgical bowel lengthening procedures may be considered. In some children with complications of parenteral nutrition, especially impending liver failure, small intestinal and liver transplantation may be considered (see Chapter 331).

Bibliography is available at Expert Consult.

338.8 Chronic Malnutrition

Raanan Shamir and David Branski

Primary malnutrition (i.e., undernutrition) is very common in developing countries and is directly related to increased disease burden and mortality (see Chapter 46). In developed countries, chronic malnutrition occurs mainly as a result of decreased food intake, malabsorption syndromes, and increased nutritional needs in children with chronic diseases. Malnutrition is diagnosed in 11–50% of hospitalized children and recent reports from Europe suggest a prevalence of close to 20% in chronically ill children. Child neglect and improper preparation of formula can result in severe malnutrition. Malnutrition can be identified by evaluating dietary intake, by medical history (anorexia, vomiting, dysphagia, mood and behavioral changes, abdominal pain, diarrhea), by anthropometric measurements (e.g., reduced weight per age and weight per height, body mass index <5th percentile), and by clinical signs of nutrient deficiencies (atrophic tongue in iron-deficiency anemia or alopecia in zinc deficiency). Screening tools for malnutrition are used in adults to provide a simple and fast way of diagnosing those patients in need. Few such screening tools for the pediatric population were developed and are being studied.

Malnourished children suffer from impaired immunity, poor wound healing, muscle weakness, and diminished psychologic drive. Malnutrition has short-term consequences (increased disability, morbidity, and mortality) and long-term consequences (final adult size, lower IQ, economic productivity). Undernutrition in hospitalized children is related to increased infectious complications, delayed recovery, increased length of stay and costs, increased readmission rates, and increased mortality.

Nutritional rehabilitation in malnourished children is discussed in Chapter 46.

Chronic malnutrition complicated by diarrheal dehydration is a commonly observed phenomenon. Infectious diarrhea is common in tropical and subtropical countries, in the setting of poor hygiene practices, in immunocompromised hosts (e.g., HIV, congenital immunodeficiency), and when impairment of the immune response is due to chronic malnutrition itself. In children with chronic disorders, diarrhea may be related to the underlying disease that should be sought for. Examples include noncompliance with a gluten-free diet in celiac disease, noncompliance with pancreatic enzyme treatment in cystic fibrosis, and disease relapse in inflammatory bowel disease (IBD). In the case of IBD, relapse should be diagnosed only after infectious diarrhea and C. difficile infection have been ruled out. Malnutrition per se can lead to exocrine pancreatic insufficiency, which, in turn, aggravates malabsorption and diarrhea.

In infants and children with severe malnutrition, many of the signs normally used to assess the state of hydration or shock are unreliable.
Bibliography
Severe malnutrition might be accompanied by sepsis; thus, children with septic shock might not have diarrhea, thirst, or sunken eyes but may be hypothermic, hypoglycemic, or febrile. The electrocardiogram often shows tachycardia, low amplitude, and flat or inverted T waves. Cardiac reserve seems lowered, and heart failure is a common complication.

Despite clinical signs of dehydration, urinary osmolality may be low in the chronically malnourished child. Renal acidifying ability is also limited in patients with malnutrition.

Management of the diarrhea in chronically malnourished children is based on 3 principles: oral rehydration to correct dehydration, rapid resumption of feeds with avoidance of periods of nothing by mouth, and treating the etiology of the diarrhea.

When treating the dehydration, it must be remembered that in dehydrated and malnourished infants there appears to be overexpansion of the extracellular space accompanied by extracellular and presumably intracellular hypoosmolality. Thus, reduced or hypotonic osmolality oral rehydration solutions are indicated in this setting. When oral rehydration is not possible, the route of choice is nasogastric, and intravenous therapy should be avoided if possible.

Initial intravenous therapy in profound dehydration is designed to improve the circulation and expand extracellular volume. For patients with edema, the quality of fluid and the rate of administration might need to be readjusted from recommended levels to avoid overhydration and pulmonary edema. Blood should be given if the patient is in shock and is severely anemic. Potassium salts can be given early if urine output is good. Clinical and electrocardiogram improvement may be more rapid with magnesium therapy.

Children with chronic malnutrition are at risk for the refeeding syndrome. Therefore, initial calorie provision should not exceed the previous daily intake and is usually begun at 50-75% of estimated resting energy expenditure, with rapid increase to caloric goals once there are no severe abnormalities in sodium, potassium, phosphorus, calcium, or magnesium. Correction of malnutrition and catch-up growth are not part of the primary treatment of these children, but a nutrition rehabilitation plan is necessary.

Bibliography is available at Expert Consult.

338.9 Enzyme Deficiencies

Michael J. Lentze and David Branski

CARBOHYDRATE MALABSORPTION

Symptoms of carbohydrate malabsorption include loose watery diarrhea, flatulence, abdominal distention, and pain. Some children are asymptomatic unless the malabsorbed carbohydrate is consumed in large amounts. Disaccharidases are present on the brush border membrane of the small bowel. Disaccharidase deficiency can be caused by a genetic defect or secondarily by damage to the small bowel epithelium, as occurs with infection or inflammatory disorders.

Unabsorbed carbohydrates enter the large bowel and are fermented by intestinal bacteria, producing organic acids and gases such as methane and hydrogen. The gases can cause discomfort and the unabsorbed carbohydrate and the organic acids cause osmotic diarrhea characterized by an acidic pH and presence of either reducing or non-reducing sugars in the stool. Hydrogen gas can be detected in the breath as a sign of fermentation of unabsorbed carbohydrates (H₂-breath test).

LACTASE DEFICIENCY

Congenital lactase deficiency is rare and is associated with symptoms occurring on exposure to lactose in milk. Fewer than 50 cases have been reported worldwide. In patients with congenital lactase deficiency, 5 distinct mutations in the coding region of the LCT gene were found. In most patients (84%), homozygosity for a nonsense mutation, 4170T-A (Y1390X; OMIM 223000), designated Fin (major), was found.

Primary adult type-hypolactasia is caused by a physiologic decline in lactase activity that occurs following weaning in most mammals. The brush-border lactase is expressed at low levels during fetal life; activity increases in late fetal life and peaks from term to 3 yr, after which levels gradually decrease with age. This decline in lactase levels varies between ethnic groups. Lactase deficiency occurs in approximately 15% of white adults, 40% of Asian adults, and 85% of black adults in the United States. Lactase is encoded by a single gene (LCT) of approximately 50 kb located on chromosome 2q21. C/T (~13910) polymorphisms of the MCM6 gene were found to be related to adult-type hypolactasia in most European populations. In 3 African populations—Tanzanians, Kenyans, and Sudanese—3 single-nucleotide polymorphisms, G/C (~14010), T/G (~13915), and C/G (~13907), were identified with lactase persistence and have derived alleles that significantly enhance transcription from the lactase gene promoter in vitro.

Secondary lactose intolerance follows small bowel mucosal damage (celiac disease, rotavirus infection) and is usually transient, improving with mucosal healing.

Lactase deficiency can be diagnosed by H₂-breath test or by measurement of lactase activity in mucosal tissue retrieved by small bowel biopsy. Diagnostic testing is not mandatory, and often simple dietary changes that reduce or eliminate lactose from the diet relieve symptoms.

Treatment of lactase deficiency consists of a milk-free diet. A lactose-free formula (based on either soy or cow's milk) can be used in infants. In older children, low-lactose milk can be consumed. Addition of lactase to dairy products usually abbreviates the symptoms.

Live-culture yogurt contains bacteria that produce lactase enzymes and is therefore tolerated in most patients with lactase deficiency. Hard cheeses have a small amount of lactose and are generally well tolerated.

FRUCTOSE MALABSORPTION

Children consuming a large quantity of juice rich in fructose, corn syrup, or natural fructose in fruit juices can present with diarrhea, abdominal distention, and slow weight gain. Restricting the amount of juice in the diet resolves the symptoms and helps avoid unnecessary investigations. Fructose H₂ breath test can be helpful in the diagnosis of fructose malabsorption. The reason for fructose malabsorption is the reduced abundance of GLUT-5 transporter on the surface of the intestinal brush-border membrane, which occurs in approximately 5% of the population.

SUCRASE-ISOMALTASE DEFICIENCY

Sucrase–isomaltase deficiency is a rare autosomal recessive disorder with a complete absence of sucrase and reduced maltase digestive activity. The sucrase–isomaltase complex is composed of 1,927 amino acids encoded by a 3,364 bp messenger RNA. The gene locus on chromosome 3 has 30 exons spanning 106.6 kb. The majority of sucrase–isomaltase mutations result in a lack of enzyme protein synthesis (null mutation). Posttranslational processing defects are also identified.

Approximately 2% of Europeans and Americans are mutant heterozygote. Sucrase deficiency is especially common in indigenous Greenlanders (estimated 5%) in whom it is often accompanied by lactase deficiency.

Symptoms of sucrase–isomaltase deficiency usually begin when the infant is exposed to sucrose or a glucose polymer diet. This can occur with ingestion of non–lactose-based infant formula or on the introduction of pureed food, especially fruits and sweets. Diarrhea, abdominal pain, and poor growth are observed. Occasional patients present with symptoms in late childhood or even adult life, but careful history often indicates that symptoms appeared earlier. Diagnosis of sucrase–isomaltase malabsorption requires acid hydrolysis of stool for reducing substances because sucrose is a nonreducing sugar. Alternatively, diagnosis can be achieved with hydrogen breath test or direct enzyme assay of small bowel biopsy.

The mainstay of treatment is lifelong dietary restriction of sucrose-containing foods. Enzyme replacement with a purified yeast

**Bibliography**

GLUCOSE–GALACTOSE MALABSORPTION

More than 30 different mutations of the sodium/glucose cotransporter gene (SGLT1) are identified. These mutations cause a rare autosomal recessive disorder of intestinal glucose and galactose/Na⁺ cotransport system that leads to osmotic diarrhea. Because most dietary sugars are poly saccharides or disaccharides with glucose or galactose moieties, diarrhea follows the ingestion of glucose, breast milk, or conventional lactose-containing formulas. Dehydration and acidosis can be severe, resulting in death.

The stools are acidic and contain sugar. Patients with the defect have normal absorption of fructose, and their small bowel function and structure are normal in all other aspects. Intermittent or permanent glycosuria after fasting or after a glucose load is a common finding because of the transport defect also being present in the kidney. The presence of reducing substances in watery stools and slight glycosuria despite low blood sugar levels is highly suggestive of glucose–galactose malabsorption. Malabsorption of glucose and galactose is easily identified using the breath hydrogen test. It is safe to perform the first test with a dose of 0.5 g/kg of glucose; if necessary, a second test can be performed using 2 g/kg. Breath H₂ will rise more than 20 ppm. The small intestinal biopsy is useful to document a normal villous architecture and normal disaccharidase activities. The identification of mutations of SGLT1 makes it possible to perform prenatal screening in families at risk for the disease.

Treatment consists of rigorous restriction of glucose and galactose. Fructose, the only carbohydrate that can be given safely, should be added to a carbohydrate-free formula at a concentration of 6–8%. Diarrhea immediately ceases when infants are given such a formula. Although the defect is permanent, later in life, limited amounts of glucose, such as starches or sucrose may be tolerated.

SEXOCRINE PANCREATIC INSUFFICIENCY

Chapter 349 discusses disorders of exocrine pancreatic insufficiency. Cystic fibrosis is the most common congenital disorder associated with exocrine pancreatic insufficiency. Although rare, the next most common cause of pancreatic insufficiency in children is Shwachman-Diamond syndrome. Other rare disorders causing exocrine pancreatic insufficiency are Johanson-Blizzard syndrome (severe steatorrhea, aplasia of alae nasi, deafness, hypothyroidism, scalp defects), Pearson bone marrow syndrome (sideroblastic anemia, variable degree of neutropenia, thrombocytopenia), and isolated pancreatic enzyme deficiency (lipase, colipase and lipase–colipase, trypsinogen, amylase). Deficiency of enterokinase—a key enzyme that is produced in the proximal small bowel and is responsible for the activation of trypsinogen to trypsin—manifests clinically as exocrine pancreatic insufficiency.

Autoimmune polyendocrinopathy syndrome type 1, a rare autosomal recessive disorder, is caused by mutation in the autoimmune regulator gene (AIRE). Chronic mucocutaneous candidiasis is associated with failure of parathyroid gland, adrenal cortex, pancreatic β cells, gonads, gastric parietal cells, and thyroid gland. Pancreatic insufficiency and steatorrhea are associated with this condition.

ENTEROKINASE (ENTEROPEPTIDASE) DEFICIENCY

Enterokinase (enteropeptidase) is a brush-border enzyme of the small intestine. It is responsible for the activation of trypsinogen into trypsin. Deficiency of this enzyme results in severe diarrhea, malabsorption, failure to thrive, and hypoproteinemic edema after birth.

Enterokinase deficiency is caused by mutation in the serine protease-7 gene (PRSS7) on chromosome 21q21. The diagnosis can be established by measuring the enzyme level in intestinal tissue. Treatment of this rare autosomal recessive disorder consists of replacement with pancreatic enzymes and administration of a protein hydrolysate formula with added MCT oil in infancy.

TRYPSINOGEN DEFICIENCY

Trypsinogen deficiency is a rare syndrome with symptomatology similar to that of enterokinase deficiency. Enterokinase catalyzes the conversion of trypsinogen to trypsin, which, in turn, activates the various pancreatic proenzymes such as chymotrypsin, procarboxypeptidase, and proelastase for their active forms. Deficiency of trypsinogen results in severe diarrhea, malabsorption, failure to thrive, and hypoproteinemic edema soon after birth.

The trypsinogen gene is encoded on chromosome 7q35. Treatment is the same as for enterokinase deficiency, with pancreatic enzymes and protein hydrolysate formula with added MCT oil in infancy.

Absorption of fats and fat-soluble vitamins depends to a great extent on adequate bile flow providing bile acids to the small intestine. Most of the liver and biliary disorders lead to impairment of the bile flow, contributing to malabsorption of long-chain fatty acids and vitamins such as A, D, E, and K. Liver disorders that are associated with significant malabsorption and failure to thrive are: (1) progressive familial intrahepatic cholestasis (types 1, 2, and 3) and bile acid synthesis defects. Progressive familial intrahepatic cholestasis type 1 is also associated with chronic diarrhea caused by bile transport defect in the gut. It is not uncommon for these children to have symptomatic fat-soluble vitamin deficiencies like pathologic fractures and peripheral neuropathy. (2) Children with storage disorders such as Wolman disease also manifest with severe failure to thrive and multiple vitamin deficiencies. (3) Children with biliary disorders such as biliary atresia after a Kasai portoenterostomy, cystic fibrosis, neonatal sclerosing cholangitis, Alagille syndrome, and sclerosing cholangitis constitute another major group of disorders where malabsorption could be a significant problem. In addition, severe portal hypertension can lead to portal hypertensive enteropathy, resulting in poor absorption of the nutrients. Decompen sated liver disease leads to anorexia and increased energy expenditures, further widening the gap between calorie intake and net absorption, leading to severe malnutrition. Adequate management of nutrition is essential to improve the outcome with or without liver transplantation. This is usually achieved by using MCT-rich milk formula, supplemental vitamins, and continuous or bolus enteral feed where oral intake is poor.

Vitamin D deficiency is commonly observed on biochemical tests, and children rarely present with pathologic fractures. Simultaneous administration of vitamin D with the water-soluble vitamin E preparation (TPGS 1,000 succinate) enhances absorption of vitamin D. In young infants, oral vitamin D₃ is given at a dose of 1,000 IU/kg/24 hr. After 1 mo, if the serum 25-hydroxyvitamin D level is low, the same dose of oral vitamin D is mixed with TPGS. 25-Hydroxyvitamin D is then monitored every 3 mo, with adjustment of doses as necessary.

Vitamin E deficiency in patients with chronic cholestasis is not usually symptomatic, but it can manifest as a progressive neurologic syndrome, which includes peripheral neuropathy (manifesting as loss of deep tendon reflexes and ophthalmoplegia), cerebellar ataxia, and posterior column dysfunction. Early in the course, findings are partially reversible with treatment; late features might not be reversible. It may be difficult to identify vitamin E deficiency because the elevated blood lipid levels in cholestatic liver disease can falsely elevate the serum vitamin E level. Therefore, it is important to measure the ratio of serum vitamin E to total serum lipids; the normal level for patients younger than 12 yr of age is >0.6, and for patients older than 12 yr it is >0.8. The neurologic disease can be prevented with the use of an oral water-soluble vitamin E preparation (TPGS, Liqui-E) at a dose of 25–50 IU/day in neonates and 1 IU/kg/day in children.

Vitamin K deficiency can occur as a result of cholestasis and poor fat absorption. In children with liver disease it is very important to
differentiate between the coagulopathy related to vitamin K malabsorption and one secondary to the synthetic failure of the liver. A single dose of vitamin K administered intravenously does not correct the prolonged prothrombin time in liver failure, but the deficiency state responds within a few hours. Easy bruising may be the first sign. In neonatal cholestasis, coagulopathy as a result of vitamin K deficiency can manifest with intracranial bleeds with devastating consequences, and prothrombin time should be routinely measured to monitor for deficiency in children with cholestasis. All children with cholestasis should receive vitamin K supplements.

Vitamin A deficiency is rare and is associated with night blindness, xerophthalmia, and increased mortality if patients contract measles. Serum vitamin A levels should be monitored and adequate supplementation considered.

338.11 Rare Inborn Defects Causing Malabsorption
Klaus-Peter Zimmer and David Branski

Some congenital (primary) malabsorption disorders originate from a defect of integral membrane proteins, which fulfill a transport function as receptor or channel across the apical or basolateral membrane of enterocytes for nutritional components. Histologic examination of the small and large bowel is typically normal. Most of these disorders are inherited in an autosomal recessive pattern. Most are rare, and patients present with a broad phenotypic heterogeneity as a result of modifier genes and nutritional and other secondary factors.

DISORDERS OF CARBOHYDRATE ABSORPTION
Patients with Fanconi-Bickel syndrome present with tubular nephropathy; rickets; hepatomegaly; glycogen accumulation in liver, kidney, and small bowel; failure to thrive; and fasting hypoglycemia. The disorder is caused by homozygous mutations of GLUT2, the facilitative glucose (and galactose) transporter at the basolateral membrane of enterocytes hepatocytes, renal tubules, pancreatic islet cells, and cerebral neurons. Because severe osmotic diarrhea is not a feature of Fanconi-Bickel syndrome, a GLUT2-independent basolateral transport for glucose is suggested. GLUT2 seems to modulate insulin secretion, renal reabsorption, and glucose uptake from the apical membrane of enterocytes in response to the (postprandial) sugar environment. Diagnostic signs are elevated galactose levels in the blood (found in the neonatal screening program), neonatal bilateral cataracts, marked glycogenuria, generalized aminoaciduria, and excessive renal losses of phosphate and calcium. Liver and kidneys are enlarged. Therapy includes substitution of electrolyte losses and vitamin D and supplying uncooked cornstarch to prevent hypoglycemia. Patients who present in the neonatal period need frequent small meals and galactose-free milk.

DISORDERS OF AMINO ACID AND PEPTIDE ABSORPTION
Owing to their ontogenic origins, enterocytes and renal tubules express amino acid transporter activity is found in the jejunum. The transporters causing Hartnup disease, cystinuria, iminoglycinuria, and dicarboxylic aminoaciduria are located in the apical membrane, and those causing lysinuric protein intolerance (LPI) and blue diaper syndrome are anchored in the basolateral membrane of the intestinal epithelium.

Dibasic amino acids, including cystine, ornithine, lysine, and arginine are taken up by the Na-independent SLCA3A1/SLC7A9, which is defective in cystinuria. The overall prevalence of the disease is 1 in 7,000 newborns. This disorder is not associated with any GI or nutritional consequences because of compensation by alternative transporters. However, hypersecretion of cystine in the urine leads to recurrent cystine stones, which account for up to 1% of all urinary tract stones. Ample hydration, urine alkalinization, and cystine-binding thiol drugs can increase the solubility of cystine. Cystinuria type I is inherited as an autosomal recessive trait, and the transmission of type II is autosomal dominant with incomplete penetrance. Cystinuria type I has been described in association with 2p21 deletion syndrome and hypotonia–cystinuria syndrome.

Hartnup disease is characterized by malabsorption of neutral amino acids, including the essential amino acid tryptophan, with aminoaciduria, photosensitive pellagra-like rash, headaches, cerebellar ataxia, delayed intellectual development, and diarrhea. The clinical spectrum ranges from asymptomatic patients to severely affected patients with progressive neurodegeneration leading to death by adolescence. SLC6A19, which is the major luminal sodium-dependent neutral amino acid transporter of small intestine and renal tubules, has been identified as the defective protein. Its association with collectrin and angiotensin-converting enzyme II is likely to be involved in the phenotypic heterogeneity of Hartnup disorder. Tryptophan is a precursor of nicotinamide adenine dinucleotide phosphate biosynthesis; therefore the disorder can be treated by nicotinamide in addition to a diet of 4 g protein/kg. The use of lipid-soluble esters of amino acids and tryptophan ethylester has also been reported.

In the blue diaper syndrome (indicurian, Drummond syndrome) tryptophan is specifically malabsorbed and the defect is expressed only in the intestine and not in the kidney, in contrast to Hartnup disease. Intestinal bacteria convert the unabsorbed tryptophan to indican, which is responsible for the bluish discoloration of the urine after its hydrolysis and oxidation. Symptoms can include digestive disturbances such as vomiting, constipation, poor appetite, failure to thrive, hypercalcemia, nephrocalcinosis, fever, irritability, and ocular abnormalities. The molecular genetic defect of this disorder has not yet been characterized.

The underlying defect of iminoglycinuria is the malabsorption of proline, hydroxyproline, and glycine as a consequence of the proton amino acid transporter SLC6A2 defect, with a possible participation of modifier genes, one of which (SLC6A20) is present in the intestinal epithelium. This disorder is usually benign, but sporadic cases with encephalopathy, mental retardation, deafness, blindness, kidney stones, hypertension, and gyrate atrophy have been described.

The excitatory amino acid carrier SLC1A1 is affected in dicarboxylic aminoaciduria, which is present in the small intestine, kidney, and brain, and transports the anionic acids γ-glutamate, α- and δ-aspartate, and α-cysteine. There are single case reports indicating that this disorder could be associated with hyperprolinemia and neurologic symptoms such as POLIP (polyneuropathy, ophthalmoplegia, leukoencephalopathy, intestinal pseudoobstruction syndrome).

A histidine-specific transport system has also been proposed. A few patients have been reported with an intestinal and renal defect of this carrier. It has not been confirmed that patients with histidinuria, who have low plasma histidine levels, in contrast to histidinemia, develop neurologic symptoms (e.g., hearing loss, myoclonic seizures).

A methionine-prefering transporter in the small intestine was suggested to be affected in Smith-Strang disease (oasthouse urine disease), which is characterized by purple, red-brown-colored urine with a cabbage-like odor, containing 2-hydroxybutyric acid, valine, and leucine. The potential symptoms of methionine malabsorption include neurologic signs, white hair, and diarrhea. Large amounts of methionine and branched-chain amino acids are present in the feces but not in the urine. A low-methionine diet is recommended to alleviate the symptoms.

Among the diseases (see the earlier discussion of cystinuria) with a membrane transport defect of cationic amino acids (lysine, arginine, ornithine), LPI is the second most common, with a prevalence in Finland of 1 in 60,000. The γ-LAT-1 (SLC7A7) carrier at the basolateral membrane of the intestinal and renal epithelium is affected, with failure to deliver cytosolic dibasic cationic amino acids into the paracellular space in exchange for Na+ and neutral amino. This defect is not compensated by the SLC3A1/SLC7A9 transporter (at the apical membrane), the latter being affected in cystinuria. The symptoms of
LPI, which appear after weaning, include diarrhea, failure to thrive, heptosplenomegaly, nephritis, respiratory insufficiency, alveolar proteinosis, pulmonary fibrosis, and osteoporosis. Abnormalities of bone marrow have also been described in a subgroup of LPI patients. The disorder is characterized by low plasma concentrations of dibasic amino acids (in contrast to high levels of citrulline, glutamine, and alanine) and massive excretion of lysine (as well as orotic acid, ornithine, and arginine in moderate excess) in the urine. Hyperammonemia and coma usually develop after episodic attacks of vomiting, after fasting, or following administration of large amounts of protein (or alanine load), possibly because of a deficiency of intramitochondrial ornithine. Some patients show moderate retardation. Cutaneous manifestations can include alopecia, perianal dermatitis, and sparse hair. Some patients avoid protein-containing food. Treatment includes orally administered citrulline (200 mg/kg/day), which is well absorbed from the intestine; dietary protein restriction (<1.5 g/kg/day); and carni­tine supplementation. One patient with isolated lysisinuria has been reported with growth failure, seizures, and mental retardation.

**DISORDERS OF FAT TRANSPORT**

Chapter 86 describes abetaliproteinemia, hypobetaliproteinemia, and chylomicron retention disease. The long-chain fatty acid (FAT4) and cholesterol transporters, the latter being called Niemann-Pick C1-like protein (NPC1L1), have been characterized at the intestinal brush-border in knockout mice models showing a hyperproliferative hyperkeratosis and an impaired fatty acid and cholesterol uptake. NPC1L1 is inhibited by ezetimibe, which is used to restrict the absorption of dietary cholesterol.

Tangier disease is characterized by the absence of high-density lipoprotein cholesterol, which is caused by mutations in the adenose triphosphate-binding cassette transporter A1 (ABCA1) gene. The failure of intracellular phospholipids and cholesterol efflux to lipoprotein acceptors such as high-density lipoprotein predisposes to premature coronary heart disease and accumulation of cholesterol in liver, spleen, lymph nodes (tonsils), and small intestine.

Features of Tangier disease include orange tonsils, heptosplenomegaly, relapsing neuropathy, orange-brown spots on the colon and ileum, diarrhea in association with decreased plasma cholesterol levels (apolipoprotein A-1 and A-II), and normal or elevated triglyceride levels. Specific therapy for Tangier disease has not yet been established.

In sitosterolemia, defective efflux of sterol leads to increased absorption of dietary sterols; normally, <5% are retained by the GI tract. Patients carry mutations of the ABCG5 (sterolin-1) and ABCG8 (sterolin-2) transporters. The disorder is associated with tendon xanthomas, increased atherosclerosis, and hemolysis. Plasma levels of phytosterols (mainly sitosterol) are typically >10 mg/dL.

Con genital diarrhea in newborns with hyperlipidemia may indicate impaired fat (bile) absorption and mutations of the microsomal enzyme acyl-coenzyme A:diacylglycerol acyltransferase 1 (DGAT1), which catalyzes the final step in triglyceride synthesis.

**DISORDERS OF VITAMIN ABSORPTION**

Transporters and receptors of the intestinal epithelium have been described for water-soluble but not fat-soluble vitamins, the latter being absorbed primarily by enterocytes, by passive diffusion after emulsification of fats by bile salts. Transferrin proteins (retinol-binding protein, RBP4, and α-tocopherol transfer protein, TTP1) have been involved in deficiency states of vitamins E (spinocerebellar ataxia) and A (ophthalmologic signs), respectively.

Vitamin B₁₂ (cobalamin) is used exclusively by microorganisms and is acquired mostly from meat and milk. Its absorption starts with the removal of cobalamin from dietary protein by gastric acidity and its binding to haptocorrin. In the duodenum, pancreatic proteases hydrolyze the cobalamin-haptocorrin complex, allowing the binding of cobalamin to intrinsic factor (IF), which originates from parietal cells. The receptor of the cobalamin-IF complex is located at the apical membrane of the ileal enterocytes and represents a heterodimer consisting of cubulin and amnionless, with endocytic uptake of this ligand into endosomes, where it binds to megalin and forms a cobalamin–transcobalamin-2 complex (after cleavage of IF) for further transcytosis. As a cofactor for methionine synthase, cobalamin converts homocysteine to methionine. Cobalamin deficiency can be caused by inadequate intake of the vitamin (e.g., breastfeeding by mothers on a vegetarian diet), primary or secondary achlorhydria including autoimmune gastritis, exocrine pancreatic insufficiency, bacterial overgrowth (see Chapter 338.4), ileal disease (Crohn disease, see Chapter 336), ileal (or gastric) resection, infections (fish tapeworm), and Whipple disease (see Chapter 341).

Clinical signs of congenital cobalamin malabsorption, which usually appear from a few mo to 14 yr of age, are pancytopenia including megaloblastic anemia, fatigue, failure to thrive, and neurologic symptoms, including developmental delay. Recurrent infections and bruising may be present. Laboratory evaluation indicates low serum cobalamin, hyperhomocysteineinemia, methylmalonic acidemia, and mild proteinuria. The Schilling test is useful to differentiate between lack of IF and malabsorption of cobalamin. Three rare autosomal recessive disorders of congenital cobalamin deficiency affect absorption and transport of cobalamin (in addition to 7 other inherited defects of cobalamin metabolism). These include mutations of the gastric IF (GIF) gene with absence of IF (but normal acid secretion and lack of autoantibodies against IF or parietal cells), mutations of the amnionless (AMN) and cubin (CUBN) genes (Imerslund-Grasbeck syndrome), and mutations in the transcobalamin 2 cDNA. These disorders require long-term parenteral cobalamin treatment: intramuscular injections of hydroxycobalamin 1 mg daily for 10 days and then once a month. High-dose substitution with oral cyanocobalamin (1 mg biweekly) does not seem to be sufficient for all patients with congenital cobalamin deficiency.

Folate is an essential vitamin required to synthesize methionine from homocysteine. It is found mainly in green leafy vegetables, legumes, and oranges. It is converted to 5-methyltetrahydrofolate after its uptake by enterocytes. Secondary folate deficiency is caused by insufficient folate intake, villous atrophy (e.g., celiac disease, IBD), treatment with phenytoin, and trimethoprim, among others (see Chapter 448.1). Several inherited disorders of folate metabolism and transport have been described.

Hereditary folate malabsorption is characterized by a defect of the proton-coupled folate transporter (formerly reported to be HCP1, a heme carrier) of the brush-border, leading to impaired absorption of folate in the upper small intestine as well as impaired transport of folate into the central nervous system. Mutations of the reduced folate carrier (RFC1, SLC19A1) have not been found in this entity. Sulfasalazine and methotrexate are potent inhibitors of proton-coupled folate transporter. Symptoms of congenital folate malabsorption are diarrhea, failure to thrive, megaloblastic anemia (in the 1st few mo of life), glossitis, infections (Pneumocystis jiroveci) with hypoinmunoglobulinemia, and neurologic abnormalities (seizures, mental retardation, and basal ganglia calcifications). Macrocytosis, with or without neutropenia, multilobulated polymorphonuclear cells, increased lactate dehydrogenase and bilirubin, increased saturation of transferrin, and decreased cholesterol can be found. Low levels of folate are present in serum and cerebrospinal fluid. Plasma homocysteine concentrations as well as urine excretion of formiminoglutamic acid and orotic acid are elevated. Long-lasting deficiency is best documented using red cell folate. Therapy involves large doses of oral (up to 100 mg/day) or systemic (intrathecal) folate.

The molecular basis of intestinal transport of other water-soluble vitamins such as vitamin C (Na+-dependent vitamin C transporters 1 and 2), pyridoxine/vitamin B₆ and biotin/vitamin B₁₂ (Na+-dependent multivitamin transporter) have been described; however congenital defects of these transporter systems have not yet been found in humans. A thiamine/vitamin B₁₂-responsive megaloblastic anemia syndrome, which is associated with early-onset type 1 diabetes mellitus and sensorineural deafness, is caused by mutations of the thiamine transporter protein, THTR-1 (SLC19A2), present in the brush-border.

The digestive system...
**DISORDERS OF ELECTROLYTE AND MINERAL ABSORPTION**

**Congenital chloride diarrhea** belongs to the more common causes of severe congenital diarrhea, with prevalence in Finland of 1:20,000. It is caused by a defect of the SLC26A3 gene, which encodes a Na⁺-independent Cl⁻/HCO₃⁻ exchanger within the apical membrane of ileal and colonic epithelium. Founder mutations have been described in Finnish, Polish, and Arab patients: V317del, I675-676ins, and G187X, respectively. The Cl⁻/HCO₃⁻ exchanger absorbs chloride originating from gastric acid and the cystic fibrosis transmembrane conductance regulator and secretes bicarbonate into the lumen, neutralizing the acidity of gastric secretion.

Prenatal clinical signs of this disorder are a dilated small bowel that can mislead to a diagnosis of intestinal obstruction. Newborns with congenital chloride diarrhea present with severe life-threatening secretory diarrhea during the 1st few wk of life. Laboratory findings are metabolic alkalosis, hypocholesteremia, hypokalemia, and hyponatremia (with high plasma renin and aldosterone activities). Fecal chloride concentrations are >90 mmol/L and exceed the sum of fecal sodium and potassium. Early diagnosis and aggressive lifelong enteral substitution of KCl in combination with NaCl (chloride doses of 6-8 mmol/kg/day for infants and 3-4 mmol/kg/day for older patients) prevent mortality and long-term complications (such as urinary infections, hyperuricemia with renal calcifications, renal insufficiency, and hypertension) and allow normal growth and development. Orally administered proton pump inhibitors, cholestyramine, and butyrate can reduce the severity of diarrhea. The diarrheal symptoms usually tend to regress with age. However, febrile diseases are likely to exacerbate symptoms as a consequence of severe dehydration and electrolyte imbalances. (See Chapter 52 for fluid and electrolyte management.)

The classic form of **congenital sodium diarrhea** manifests with polyhydramnios, massive secretory diarrhea, severe metabolic acidosis, alkaline stools (fetal pH >7.5) and hyponatremia as a result of fecal losses of Na⁺ (fecal Na⁺ >70 mmol/L). Urinary secretion of sodium is low to normal. There is partial villous atrophy. The molecular genetic defect could not be located in the Na⁺-H⁺ exchangers, which were thought to be impaired because they seem to be mainly responsible for Na⁺ absorption in the small intestine. In addition, a syndromic form of congenital sodium diarrhea with chonaal or anal atresia, hypertelorism, and corneal erosions has been related to mutations of SINT2, encoding a serine–protease inhibitor, whose pathophysiologic action on intestinal Na⁺ absorption is unclear. Some patients can be weaned from parenteral nutrition later in childhood but depend on oral sodium citrate supplementation.

The congenital form of **acrodermatitis enteropathica** manifests with severe deficiency of body zinc soon after birth in bottle-fed children or after weaning from breastfeeding. Clinical signs of this disorder are anorexia, diarrhea, failure to thrive, harmonic and cell-mediated immunodeficiency (poor wound healing, recurrent infections), male hypogonadism, skin lesions (vesicobullous dermatitis on the extremities and perirectal, perigential, and perioral regions, and alopecia), and neurologic abnormalities (tremor, apathy, depression, irritability, nystagmus, photophobia, night blindness, and hypoguesia). The genetic defect of acrodermatitis enteropathica is caused by a mutation in the Zrt-Irt-like protein 4 (ZIP4, SLC39A4), normally expressed on the apical membrane, which enables the uptake of zinc into the cytosol of enterocytes. The zinc-dependent alkaline phosphatase and plasma zinc levels are low. Paneth cells in the crypt of the small intestinal mucosa show inclusion bodies. Acrodermatitis enteropathica requires long-term treatment with elemental zinc 1 mg/kg/day. Maternal zinc deficiency impairs embryonic, fetal, and postnatal development. Chapter 51 describes the acquired forms of zinc deficiency.

**Menkes disease** and **ocipital horn syndrome** are both caused by mutations in the gene encoding Cu²⁺-transporting adenosine triphosphatase (ATPase), α-polypeptide (ATP7A), also called Menkes or MNK protein. ATP7A is mainly expressed by enterocytes, placental cells, and the central nervous system, and is localized in the trans-Golgi network for copper transfer to enzymes in the secretory pathway or to endosomes to facilitate copper efflux. Copper values in liver and brain are low in contrast to an increase in mucosal cells, including enterocytes and fibroblasts. Plasma copper and ceruloplasmin levels decline postnatally. Clinical features of Menkes disease are progressive cerebral degeneration (convulsions), feeding difficulties, failure to thrive, hypothermia, apnea, infections (urinary tract), peculiar facies, hair abnormalities ( kinky hair), hypopigmentation, bone changes, and cutis laxa. Patients with the classic form of Menkes disease usually die before the age of 3 yr. A therapeutic trial with copper-histidinase should start before the age of 6 wk. In contrast to Menkes disease, occipital horn syndrome usually manifests during adolescence with borderline intelligence, craniofacial abnormalities, skeletal dysplasia (short clavicles, pectus excavatum, genu valgum), connective tissue abnormalities, chronic diarrhea, orthostatic hypotension, obstructive uropathy, and osteoporosis. It should be differentiated from Ehlers-Danlos syndrome type V.

Active **calcium** absorption is mediated by the transient receptor potential channel 6 (TRPV6) at the brush border membrane, calbindin, and the CaATPase, or the Na⁺-Ca⁺ exchanger for calcium efflux at the basolateral membrane within the proximal small bowel. A congenital defect of these transporters has not yet been described.

Intestinal absorption of dietary magnesium, which occurs via the transient receptor potential channel TRPM6 at the apical membrane, is impaired in familial **hypomagnesemia with secondary hypocalcemia**, which manifests with neonatal seizures and tetany.

Intestinal iron absorption consists of several complex regulated processes starting with the uptake of heme-containing iron by heme carrier protein 1 (HCPI) and Fe⁺² (after luminal reduction of oxidized Fe⁺³) by the divalent metal transporter 1 (DMT1) at the apical membrane, followed by the efflux of Fe⁺³ by ferroportin 1 (also called iron-regulated transporter) at the basolateral membrane of duodenal enterocytes. Mutations of the ferroportin 1 gene have been found in the autosomal dominant form of **hemochromatosis type 4**. Mutations of HFE (Cys282Tyr, His63Asn, Ser65Cys) of classic hemochromatosis reduce the endocytic uptake of diferic transferrin by the transferrin receptor-1 at the basolateral membrane of the intestinal epithelium. Hepcidin antimicrobial peptide encodes hepcidin, a hepatic peptide hormone, which inhibits the efflux of iron through ferroportin and can be induced by IL-6. It is the defective gene of juvenile hemochromatosis (type 2, subtype B).

**338.12 Malabsorption in Eosinophilic Gastroenteritis**

Ernest G. Seidman and David Branski

Eosinophilic digestive diseases are a group of rare and heterogeneous conditions characterized by patchy or diffuse eosinophilic infiltration of GI tissue. The diagnosis of eosinophilic gastroenteritis is based on GI symptoms, GI eosinophilic infiltrates, and the absence of other causes such as parasitic infection (most commonly *Enterobius vermicularis* in children) or a specific allergic response. Peripheral eosinophilia and elevated serum IgE levels are variably present are not diagnostic criteria. The majority (50-70%) of patients have a history of other allergic disorders, and others might have associated connective tissue diseases. Approximately 10% of patients with this disorder have an immediate family member affected, suggesting that eosinophilic GI disorders stem from a genetic predisposition, common environmental factors, or, most likely, a combination. Hypersensitivity to specific food allergens has been postulated as an etiologic factor. Symptoms depend on the severity and location of eosinophilic inflammation. Any region or layer (mucosa, submucosa, and serosa) of the gut may be involved, alone or in combination.

Diagnosis requires pan-endoscopy with biopsies. Eosinophilic infiltrates dominate the histologic findings, and signs of other inflammatory diseases are absent; in particular, the crypt architecture remains normal, no parasites are identified, and no eggs or larvae are found.
Chapter 338 Disorders of Malabsorption

Full text: Bibliography

An increase in mast cells and IgE-containing plasma cells may be observed. Mucosal biopsies will only establish the diagnosis in cases with mucosal involvement. Small bowel capsule endoscopy is often very useful in that it characteristically reveals denuded mucosal erythema with marked focal villous atrophy in areas out of reach of standard endoscopes. The most common sites of involvement are the stomach and small intestine.

Symptoms may include abdominal pain (90%), vomiting (60%), nausea (50%), and abdominal distention (50%). Diarrhea with weight loss because of malabsorption can occur if small bowel involvement with villous blunting is extensive. Other than peripheral eosinophilia, hypoalbuminemia as a result of protein-losing enteropathy and iron-deficiency anemia are the more common laboratory findings.

Nutritional exclusion (or elemental) diets and corticosteroids are the mainstay of treatment. Approximately 50% of cases are complex, characterized by unpredictable relapses and a chronic course. Less-well-documented treatments, such as mast cell stabilizers and leukotriene antagonists (montelukast), have been used in small, uncontrolled trials. Clinical trials using biological modalities such as monoclonal anti-IgE (omalizumab) and anti-IL-5 (SCH55700/reslizumab and mepolizumab) are anticipated for severe cases.

### 338.13 Malabsorption in Inflammatory Bowel Disease

*Ernest G. Seidman and David Branski*

Crohn disease and ulcerative colitis represent the 2 forms of chronic, immune-mediated IBD that commonly affect pediatric patients (see Chapter 336). Because the small bowel is involved in the majority of pediatric Crohn disease patients, malabsorption of nutrients is far more of a problem than in ulcerative colitis. At the time of diagnosis, significant weight loss is observed in up to 85% of pediatric patients with Crohn disease and in approximately 65% with ulcerative colitis, due to inadequate intake of energy and micronutrients as well as diarrhea and malabsorption. Consequently, growth failure as a consequence of chronic undernutrition is far more common in Crohn disease than in ulcerative colitis, affecting up to 40% of cases.

In addition to malabsorption, energy intake is lower in patients with Crohn disease compared to healthy controls, in part due to lesser appetite. Excessive levels of proinflammatory cytokines are implicated in causing the anorexia as well as in mediating impaired growth. The symptoms, including abdominal pain, nausea, vomiting, and diarrhea, can cause affected children to have a lower desire to eat, which can lead to reduced food intake. This can, in turn, negatively affect nutritional status during a child’s critical period of growth and development.

Patients with IBD are also at risk of developing nutritional deficiencies because of restrictive diets imposed by caregivers or by the patients themselves.

In children with active disease, inadequate intakes of energy and of a number of micronutrients have been observed. Reduced energy intake during active disease can contribute to poor weight gain and impaired growth. Patients with IBD, particularly Crohn disease, often have multiple nutritional deficiencies and may be in negative nitrogen balance because of decreased intake and malabsorption of macro- and micronutrients. Quantifying nutrient intake, determining micronutrient deficiencies, and ascertaining requirements for nutritional supplementation are essential components of successful management in pediatric IBD.

Optimizing nutritional status and growth are key priorities in the management of IBD in children and adolescents. Energy intake should meet the added costs of catch-up growth and are usually in the range of 40-70 kcal/kg ideal body weight per day. Protein requirements are higher in Crohn disease (1-1.5 g/kg/day). Bone mineral density deficit is common, even in pediatric patients who have not been exposed to systemic corticosteroid therapy. Osteoporosis or osteopenia is best assessed by bone densitometry, and levels of vitamin 25-hydroxvitamin D should be monitored. Table 338-10 shows other micronutrient deficiencies that result from inadequate intake, malabsorption, and gut losses.

Bile acid malabsorption is common in ileal Crohn disease, especially after small bowel resection. This leads to diarrhea and also places patients at increased risk for urolithiasis and cholelithiasis. The prevalence of recurrent calcium-oxalate urolithiasis is up to 5-fold higher in Crohn disease. Increased urinary oxalate and decreased citrate excretion, resulting from bowel resection with mainly preserved colon, were identified as crucial risk factors for stone formation. The hyperoxaluria predominantly results from increased colonic permeability to oxalate due to disturbed bile acid metabolism.

Enteral nutrition support is favored over parenteral for all but Crohn disease patients with extreme short gut. To induce remission, exclusive nutritional therapy given orally was reported to be as effective as when continuously administered by enteral feeding tube. However, weight gain was significantly greater for the latter group. Patients requiring hospitalization for a severe relapse should receive nutrition support if they are already malnourished or their intake is likely to be severely curtailed for ≥1 wk. Preoperative nutrition support is essential to the prevention of morbidity and mortality. However, clinicians must be aware of the risk of the refeeding syndrome in patients with severe malnutrition. In ulcerative colitis, nutrition support is adjunctive therapy; there is no evidence that bowel rest or total parenteral nutrition parenteral nutrition influences the outcome of severe ulcerative colitis.

Bibliography
The introduction of tacrolimus and the development of the abdominal multiorgan procurement techniques allowed the tailoring of various types of intestine grafts that can contain other intraabdominal organs, such as the liver, pancreas, and stomach; this has been critical to the application of this type of organ transplant. The understanding that the liver protects the intestine against rejection demonstrates the interaction between recipient and donor immunocytes (host-versus-graft and graft-versus-host) which under the cover of immunosuppression allows varying degrees of graft acceptance and eventual minimization of drug therapy. Over the past several years the number of patients placed on the list for and those undergoing intestinal transplantation has decreased, which may be a result of (1) improvements in the care of patients with intestinal failure under a multidisciplinary intestinal care team management, (2) the introduction of new lipid management strategies for the treatment of cholestatic liver disease, and (3) corrective surgery enhancing absorptive surface and motility.

**INDICATIONS FOR INTESTINAL TRANSPLANT**

Intestinal failure describes a patient who has lost the ability to maintain nutritional support and adequate fluid requirements, needed to sustain growth, with their own intestine and is permanently dependent on total parenteral nutrition (TPN). The majority of these patients have short bowels as a result of a congenital deficiency or acquired condition (see Chapter 338.7). In others, the cause of intestinal failure is a functional disorder of motility or absorption (Table 339-1). Rarely do patients receive intestinal transplants for benign neoplasms. The complications of intestinal failure include loss of venous access, life-threatening infections, and TPN-induced cholestatic liver disease.

**Paucity of Venous Access**

Administration of TPN requires the insertion of a centrally placed venous catheter, there being only 6 readily accessible sites (bilateral internal jugulars, subclavians, iliac veins). The loss of venous access generally occurs in the setting of recurrent catheter sepsis and thrombosis; clinical convention suggests that loss of 50% of these venous access sites places the patient at risk of not being able to be treated with TPN.

**Life-Threatening Infections**

Life-threatening infections are usually catheter-related; the absence of significant lengths of intestine may be associated with abnormal motility of the residual bowel (producing both delayed or rapid emptying), with varying degrees of bacterial overgrowth and possible bacterial or fungal translocation as a consequence of loss of intestinal barrier function and/or loss of gut immunity. This situation can produce cholestatic liver disease, multisystem organ failure, and metastatic infectious foci in lungs, kidneys, liver, and the brain.

**Liver Disease**

The development of cholestatic liver disease is the most serious complication of intestinal failure and may be a consequence of the toxic drug effects of TPN on hepatocytes, a disruption of bile flow and bile acid metabolism, and the frequent occurrence of bacterial translocation and sepsis with endotoxin release into the portal circulation. This complication varies in frequency depending on the patient’s age and the etiology of the intestinal failure; it is most common in neonates with extreme short gut. The effects on the liver include fatty transformation, steatohepatitis and necrosis, fibrosis, and then cholestasis. The development of clinical jaundice (total bilirubin >3 mg/dL) and thrombocytopenia are significant risk factors for poor outcome, because these changes portend the development of portal hypertensive gastroenteropathy, hypersplenism, coagulopathy, and uncontrollable bleeding.

**TRANSPLANTATION OPERATION**

**Donor Selection**

Intestinal grafts are usually procured from hemodynamically stable, ABO-identical brain-dead donors who have minimal clinical or laboratory evidence suggesting intraabdominal ischemia; size matching varies according to age of the recipients; present surgical techniques allow for significant reductions of the graft in order to achieve abdominal closure. Human leukocyte antigen has been random, and cross-matching has not been a determinant of graft acceptance. Exclusion criteria include a history of malignancy and intraabdominal evidence of infection; systemic viral or bacterial infections are not excluded. Donor preparation has been limited to the administration of systemic and enteral antibiotics. Propylxilysin for graft-versus-host disease with graft pretreatment using irradiation or a monoclonal antilymphocyte antibody has varied over time. Grafts have been preserved with the University of Wisconsin solution, as is the case with other types of abdominal organs.

**Types of Intestinal Grafts**

Intestinal allografts are used in various forms, either alone (as an isolated intestine graft) or as a composite graft, which can include the liver, duodenum, and pancreas (liver-intestine graft); when this composite graft includes the stomach, and the recipient operation requires the removal of all of the patient’s gastrointestinal tract (as with intestinal pseudoobstruction) and liver, then this replacement graft is known as a multivisceral graft.

The procurement of these various types of grafts focuses on the preservation of the arterial vessels of celiac and/or superior mesenteric arteries, as well as appropriate venous outflow, which would include the superior mesenteric vein or the hepatic veins in the composite grafts. The larger composite grafts inherently retain the celiac and superior mesenteric arteries; this includes multivisceral grafts, liver plus small bowel grafts, and "modified multivisceral grafts" in which the liver is excluded but the entire gastrointestinal tract is replaced.
including the stomach. The isolated intestine graft retains the superior mesenteric artery and vein; this graft can be accomplished with preservation of the vessels going to the pancreas, when that organ has been allocated to another recipient. The graft that is to be used in a particular recipient is dissected out in situ and then removed after cardiac arrest of the donor, with core cooling of the organs, using an infusion of preservation solution (Fig. 339-1).

Various modifications in these grafts have included the preservation of visceral ganglia at the base of the arteries, the inclusion of donor duodenum and pancreas for the liver and intestine graft, the inclusion of colon, the reduction of the liver graft (into left or right side) and variable reduction of the intestine graft, and the development of living donor intestine grafts.

**The Recipient Operation**

Because many children have had multiple previous abdominal operations, intestinal transplantation can be a formidable technical challenge; most children require replacement of the liver because of TPN-induced disease and often present with advanced liver failure. Transplantation of an isolated intestinal allograft involves exposure of the lower abdomen, infrarenal aorta, and inferior vena cava. Placement of vascular homografts using donor iliac artery and vein to these vessels allows arterialization and venous drainage of the intestinal graft. In patients who have retained their intestine and then undergo an enterectomy at the time of transplantation, use of the native superior mesenteric vessels is feasible.

Transplantation of a larger composite graft requires the removal and replacement of the native liver in the liver with intestine transplant, and complete abdominal exenteration in the multivisceral transplant. In a similar fashion, the infrarenal aorta is exposed for placement of an arterial conduit graft (donor thoracic aorta) for arterialization of the graft. The venous drainage is achieved to the retained hepatic veins, which are fashioned to a single conduit for anastomosis to the allograft liver.

The intestinal anastomosis to native proximal and distal bowel are performed, leaving an enterostomy of distal allograft ileum; this will be used for routine posttransplantation surveillance endoscopy and biopsy. This ostomy is closed 3-6 mo after transplantation (Fig. 339-2).

**POSTOPERATIVE MANAGEMENT**

**Immunosuppression**

Successful immunosuppression for intestinal transplantation is initiated with tacrolimus and corticosteroids. This required high levels of tacrolimus (in the nephrotoxic range), and although initial success rates were high they were followed by rejection rates of >80%, infection, and late drug toxicities, resulting in a gradual loss of grafts and patients. The next generation of protocols incorporated the addition of other agents, such as azathioprine, cyclophosphamide, induction with an interleukin-2 antibody antagonist, mycophenolate mofetil, and rapamycin. This modification resulted in a decreased incidence in the severity of initial rejection; the ability to decrease immunosuppression...
Allograft Assessment

There are no simple laboratory tools that allow assessment of the intestinal allograft. The gold standard for diagnosis of intestinal allograft rejection has been serial endoscopic surveillance and biopsies through the allograft ileostomy. Clinical signs and symptoms of rejection or infection of the allograft can overlap and mimic each other, producing either rapid diarrhea or complete ileus with pseudoobstruction syndromes, or gastrointestinal bleeding. Any changes in clinical status should warrant thorough evaluation for rejection with endoscopic biopsies and an evaluation for opportunistic infection, malabsorption, and other enteral infections.

The diagnosis of acute rejection is based on seeing destruction of crypt epithelial cells from apoptosis, in association with a mixed lymphocytic infiltrate. These histologic findings may or may not correlate with endoscopic evidence of injury, which varies from diffuse erythema and friability to ulcers and, in cases of severe rejection, exfoliation of the intestinal mucosa. Chronic rejection of the allograft can be diagnosed only through full thickness sampling of the intestine, which shows the typical vasculopathy that can result in progressive ischemia of the allograft.

Rejection and Graft-Versus-Host Disease

Acute rejection rates for the intestinal allograft are significantly higher than with any other organ, in the range of 80–90%, and severe rejection requiring the use of antilymphocyte antibody preparations may be as high as 30%. Triple-drug regimens and the use of interleukin-2 antibody inhibitors have resulted in significant decreases in rejection rates; nonetheless, the amount of immunosuppression was incompatible with improvements in long-term patient and graft survival. Rejection rates of 40% are achievable with the use of antilymphocyte globulin. These protocols induce varying degrees of “proper tolerance,” which can eventually allow for minimization of immunosuppression, thus reducing the risk of drug toxicity and infection. Vascular rejection has been an uncommon occurrence, and chronic rejection has been seen in approximately 15% of cases. Graft-versus-host disease is infrequent but potentially life-threatening. The mortality rate exceeds 80% and most recipients die from infectious complications from bone marrow failure. The incidence seen in intestinal transplantation is 5–6%. Although no standard treatment is available, early diagnosis, prevention of infection, and initiation of treatment as soon as possible may improve outcomes.

Infections

Infectious complications are the most significant cause of morbidity and mortality after intestinal transplantation. The most common infections (bacterial, fungal, polymicrobial) occur as a result of the continuing need for venous catheter placement for as long as 1 yr posttransplantation. Infections as a consequence of immunosuppressive drug management are from cytomegalovirus (CMV) infection (22% incidence), Epstein-Barr virus (EBV)–induced infections (21% incidence), and adenovirus enteritis (40% incidence). Despite improvements in monitoring and preventative measures, CMV remains the most common viral infection post–intestinal transplantation. CMV may be acquired from blood transfusions, reactivation of endogenous viruses, or the donated allograft. The highest risk recipients for CMV infection are those who are immunologically naïve and receive an allograft from a donor who is seropositive. The 2 mainstay CMV prevention strategies commonly employed are universal prophylaxis and preemptive therapy. Current consensus guidelines recommend prophylaxis treatment for high-risk patients (donor+/ recipient−). The preferred drugs for CMV prophylaxis are ganciclovir and oral valganciclovir.

Patients at the highest risk for EBV infection are similarly those who are seronegative at the time of transplantation and those requiring a high-burden immunosuppressive therapy to maintain their graft. EBV disease varies from asymptomatic viremia to posttransplant lymphoproliferative disorder (PTLD). The incidence of EBV-related PTLD is highest in patients receiving intestinal allografts compared to liver, heart, or kidney. Children have a higher incidence of PTLD compared to adults, and are most likely to have EBV+PTLD. Early diagnosis and prevention of PTLD is essential and the mainstay of therapy is to reduce immunosuppression, although some patients have required chemotherapy. The use of anti–B-cell monoclonal antibodies, such as the anti-CD20 antibody rituximab, in PTLD has been successful as noted in anecdotal reports. Successful management of these viral infections is achieved through early detection and preemptive therapy, for both CMV and EBV, before the development of a serious life-threatening infection. This approach has improved outcomes for CMV, eliminating the mortality in the pediatric patient population (see Chapters 178, 254, and 255).

Outcomes

Intestinal transplantation is the standard of care for children with intestinal failure who have significant complications of TPN and can no longer tolerate such therapy. Data from the Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) Annual Report 2011, and center-specific data reports have documented significant improvements with short- and long-term survivals for transplantations occurring principally in the last 10 yr; intestinal transplantation (liver-intestine and isolated intestinal transplants) graft failure rates for deceased donor transplants in 2010–2011 were 26% at 1 yr, 46% at 3 yr for transplants in 2008–2009, and 48% at 5 yr for transplants in 2006–2007 (Fig. 339-3). It is hoped that with the minimization strategies currently used the long-term survival will plateau as occurs with other organ transplants; rehabilitation and quality-of-life studies have shown that more than 80% of survivors reach total independence from TPN and have meaningful

![Graft Failure Among Intestinal Transplant Recipients: Deceased Donor](http://srtr.transplant.hrsa.gov/annual_reports/2011/default.aspx)
life activities. Consequently, there has been a shift in efforts to improve long-term outcomes and quality of life.

The term *gastroenteritis* denotes infections of the gastrointestinal tract caused by bacterial, viral, or parasitic pathogens (Tables 340-1 to 340-3). Many of these infections are foodborne illnesses. The most common manifestations are diarrhea and vomiting, which can also be associated with systemic features such as abdominal pain and fever. The term *gastroenteritis* captures the bulk of infectious cases of diarrhea. The term *diarrheal disorders* is more commonly used to denote infectious diarrhea in public health settings, although several noninfectious causes of gastrointestinal illness with vomiting and/or diarrhea are well recognized (Table 340-4).

**EPIDEMIOLOGY OF CHILDHOOD DIARRHEA**

Diarrheal disorders in childhood account for a large proportion (9%) of childhood deaths, with an estimated 0.71 million deaths per year globally, making it the second most common cause of child deaths worldwide. Almost 1.731 billion episodes of diarrhea occurred in 2010 in children younger than 5 yr of age in developing countries, with more than 80% of the episodes occurring in Africa and South Asia (50.5% and 32.5%, respectively) and 36 million of the total episodes progress to severe episodes. Global mortality may be declining rapidly, but the overall incidence of diarrhea has only declined from 3.4 to approximately 2.9 episodes per child-year in the past 2 decades, and it is estimated to account for 23 million childhood disability-adjusted life years.

The decline in diarrheal mortality, despite the lack of significant changes in incidence, is the result of preventive rotavirus vaccination and improved case management of diarrhea, as well as improved nutrition of infants and children. These interventions have included widespread home- and hospital-based oral rehydration therapy and improved nutritional management of children with diarrhea.

In addition to the risk of mortality, persistently high rates of diarrhea, especially prolonged and persistent diarrhea among young children may be associated with long-term adverse outcomes. Diarrheal illnesses, especially early and repeated episodes among young children can be associated with malnutrition, micronutrient deficiencies, and significant deficits in psychomotor and cognitive development.

**ETIOLOGY OF DIARRHEA**

Gastroenteritis is the result of infection acquired through the fecal–oral route or by ingestion of contaminated food or water. Gastroenteritis is associated with poverty, poor environmental hygiene, and development indices. Enteropathogens that are infectious in a small inoculum (*Shigella*, enterohemorrhagic *Escherichia coli*, *Campylobacter jejuni*, noroviruses, rotavirus, *Giardia lamblia*, *Cryptosporidium parvum*, *Entamoeba histolytica*) can be transmitted by person-to-person contact, whereas others, such as cholera, are generally a consequence of contamination of food or water supply (see Tables 340-1 to 340-3).

In the United States, rotavirus and the noroviruses (small round viruses such as Norwalk-like virus and caliciviruses) are the most common viral agents, followed by sapoviruses, enteric adenoviruses, and astroviruses (see Table 340-2). Foodborne outbreaks in the United States are mostly caused by norovirus, accounting for 58% of all episodes, and by bacterial causes, which are most commonly *Salmonella*, *Clostridium perfringens*, *Campylobacter*, and *Staphylococcus aureus*, followed much less often by *E. coli*, *Clostridium botulinum*, *Shigella*, *Cryptosporidium*, *Yersinia*, *Listeria*, *Vibrio*, and *Cyclospora* species, in that order. Food sources include poultry, leafy vegetables, beef, fruits and nuts, vine-stalk vegetables, and many other foods.

Direct person-to-person contact outbreaks of gastroenteritis are usually caused by norovirus and *Shigella* species. Unknown agents are seen in 30–40%; other pathogens include *Salmonella*, rotavirus, *Giardia*, *Cryptosporidium*, *Clostridium difficile*, and *C. jejuni*.

The exact etiologic fractions of diarrhea among children in developing countries are a subject of much research, and our knowledge of the various pathogens that cause moderate to severe childhood diarrhea has grown considerably (Fig. 340-1; Table 340-5). There are indications that rates of hospitalization and deaths caused by *Shigella* infections, especially *Shigella dysenteriae* type 1, the most severe form of shigellosis, may be declining; however, it accounts for nearly 28,000 deaths annually. Enteropathogenic *E. coli* is responsible for 79,000 and enterotoxigenic *E. coli* (ETEC) may be responsible for 42,000 deaths annually among children younger than 5 yr. Rotavirus infections (the most common identifiable viral cause of gastroenteritis in all children) account for 197,000 deaths annually or 28% of all deaths caused by diarrhea among children younger than 5 yr of age.

**PATHOGENESIS OF INFECTIOUS DIARRHEA**

Pathogenesis and severity of bacterial disease depend on whether organisms have preformed toxins (*S. aureus*, *Bacillus cereus*), produce secretory (cholera, *E. coli*, *Salmonella*, *Shigella*) or cytotoxic (*Shigella*, *S. aureus*, *Vibrio parahaemolyticus*, *C. difficile*, *E. coli*, *C. jejuni*) toxins, or are invasive, and on whether they replicate in food. Enteropathogens can lead to either an inflammatory or noninflammatory response in the intestinal mucosa (Table 340-6).

Enteropathogens elicit noninflammatory diarrhea through enterotoxin production by some bacteria, destruction of villus (surface) cells by viruses, adherence by parasites, and adherence and/or translocation by bacteria. Inflammatory diarrhea is usually caused by bacteria that directly invade the intestine or produce cytotoxins with consequent fluid, protein, and cells (erythrocytes, leukocytes) that enter the intestinal lumen. Some enteropathogens possess more than 1 virulence property. Some viruses, such as rotavirus, target the microvillus tips of the enterocytes and can enter the cells by direct invasion or calcium-dependent endocytosis. This can result in villus shortening and loss of enterocyte absorptive surface through cell shortening and loss of microvilli (Fig. 340-2).

Most bacterial pathogens elaborate enterotoxins; the rotavirus protein NSP4 acts as a viral enterotoxin. Bacterial enterotoxins can selectively activate enterocyte intracellular signal transduction and can also affect cytoskeletal rearrangements with subsequent alterations in the water and electrolyte fluxes across enterocytes. In toxigenic diarrhea, enterotoxin produced by *Vibrio cholerae*, increased mucosal levels of cyclic adenosine monophosphate, inhibit electroneutral NaCl absorption but have no effect on glucose-stimulated Na+ absorption. In inflammatory diarrhea (e.g., *Shigella* spp. or *Salmonella* spp.) there is extensive histologic damage, resulting in altered cell morphology and reduced glucose-stimulated Na+ and electroneutral NaCl absorption. The role of 1 or more cytokines in this inflammatory response is critical. In secretory cells from crypts, Cl secretion is minimal in normal subjects and is activated by cyclic adenosine monophosphate in toxicogenic and inflammatory diarrhea (Fig. 340-3).

ETEC colonizes and adheres to enterocytes of the small bowel via its surface fimbriae (pili) and induces hypersecretion of fluids and electrolytes into the small intestine through 1 of 2 toxins: the heat-labile enterotoxin or the heat-stable enterotoxin. Heat-labile enterotoxin is structurally similar to the *V. cholerae* toxin, and activates adenylate cyclase, resulting in an increase in intracellular cyclic guanosine monophosphate (Fig. 340-4). In contrast, *Shigella* spp. cause...

<td>24-48 hr</td>
<td>Abdominal cramps, fever, diarrhea Stools might contain blood and mucus</td>
<td>Food or water contaminated with human fecal material Usually person-to-person spread, fecal-oral transmission Ready-to-eat foods touched by infected food workers, e.g., raw vegetables, salads, sandwiches</td>
<td>4-7 days</td>
<td>Supportive care. Antibiotics are recommended for severe disease, bloody diarrhea, or compromised immune systems. Resistance to traditional first-line drugs like ampicillin and TMP-SMX is common. When susceptibility is unknown or when an ampicillin- or TMP-SMX-resistant strain is isolated, choices for therapy include fluoroquinolones, ceftriaxone, and azithromycin. Antidiarreal agents such as Imodium or Lomotil can worsen the illness and should be avoided</td>
<td></td>
</tr>
<tr>
<td>Staphylococcus aureus (preformed enterotoxin)</td>
<td>1-6 hr</td>
<td>Sudden onset of severe nausea and vomiting Abdominal cramps Diarrhea and fever may be present</td>
<td>Unrefrigerated or improperly refrigerated meats, potato and egg salads, cream pastries</td>
<td>24-48 hr</td>
<td>Supportive care</td>
<td></td>
</tr>

<tbody>
<tr>
<td><em>Vibrio cholerae</em> (toxin)</td>
<td>24-72 hr</td>
<td>Profuse watery diarrhea and vomiting, which can lead to severe dehydration and death within hours</td>
<td>3-7 days</td>
<td>Contaminated water, fish, shellfish, street-vended food typically from Latin America or Asia</td>
<td>Stool culture. <em>V. cholerae</em> requires special media to grow. Cary-Blair media is ideal for transport, and the selective thiosulfate-citrate-bile salts agar (TCBS) is ideal for isolation and identification.; if <em>V. cholerae</em> is suspected, must request specific testing. Commercially available rapid test kits (e.g., Crystal VC dipstick) are useful in epidemic settings but do not test susceptibility or subtype so should not be used for routine diagnosis</td>
<td>Supportive care with aggressive oral and intravenous rehydration. Doxycycline is recommended as first-line treatment for adults, whereas azithromycin is recommended as first-line treatment for children and pregnant women. Ciprofloxacin and doxycycline recommended as second-line drugs for children</td>
</tr>
<tr>
<td><em>Vibrio parahaemolyticus</em></td>
<td>2-48 hr</td>
<td>Watery diarrhea, abdominal cramps, nausea, vomiting</td>
<td>2-5 days</td>
<td>Undercooked or raw seafood, such as fish, shellfish</td>
<td>Stool cultures. <em>V. parahaemolyticus</em> requires special media (TCBS agar) to grow; must request specific testing</td>
<td>Supportive care. There is no evidence that antibiotic treatment decreases the severity or the length of the illness. Antibiotics are recommended in severe or prolonged cases: tetracycline or ciprofloxacin can be used</td>
</tr>
<tr>
<td><em>Vibrio vulnificus</em></td>
<td>1-7 days</td>
<td>Vomiting, diarrhea, abdominal pain, bacteremia, and wound infections More common and potentially fatal in the immunocompromised or in patients with chronic liver disease (presenting with septic shock and hemorrhagic bullous skin lesions)</td>
<td>2-8 days</td>
<td>Undercooked or raw shellfish, especially oysters, other contaminated seafood, and open wounds exposed to seawater</td>
<td>Stool, wound, or blood cultures. <em>V. vulnificus</em> requires special media (TCBS agar) to grow; if <em>V. vulnificus</em> is suspected, must request specific testing</td>
<td>Supportive care and antibiotics: doxycycline, and a third-generation cephalosporin such as ceftazidime is recommended</td>
</tr>
<tr>
<td><em>Yersinia enterocolitica</em> and <em>Yersinia pseudotuberculosis</em></td>
<td>24-48 hr</td>
<td>Appendicitis-like symptoms (diarrhea and vomiting, fever, abdominal pain) occur primarily in older children and young adults Might have a scarlatiniform rash or erythema nodosum with <em>Y. pseudotuberculosis</em></td>
<td>1-3 wk, usually self-limiting</td>
<td>Undercooked pork, unpasteurized milk, tofu, contaminated water Infection has occurred in infants whose caregivers handled chitterlings</td>
<td>Stool, vomitus, or blood culture, throat, lymph nodes, joint fluid, urine, and bile <em>Yersinia</em> requires special media to grow; must request specific testing Serology is available in research and reference laboratories</td>
<td>Supportive care If septicemia or other invasive disease occurs, antibiotic therapy with aminoglycosides, doxycycline, TMP-SMX, or fluoroquinolones may be useful</td>
</tr>

</table>

BAL, bronchoalveolar lavage; GI, gastrointestinal.  
gastroenteritis via a superficial invasion of colonic mucosa, which they invade through M cells located over Peyer patches. After phagocytosis, a series of events occurs, including apoptosis of macrophages, multiplication and spread of bacteria into adjacent cells, release of inflammatory mediators (interleukin-1 and -8), transmigration of neutrophils into the lumen of the colon, neutrophil necrosis and degranulation, further breach of the epithelial barrier, and mucosal destruction (Fig. 340-5).

**RISK FACTORS FOR GASTROENTERITIS**

In developed countries, episodes of infectious diarrhea can occur through seasonal exposure to organisms such as rotavirus, or exposure to pathogens in settings of close contact (e.g., daycare centers). Major risks include environmental contamination and increased exposure to enteropathogens. Additional risks include young age, immunodeficiency, measles, malnutrition, and lack of exclusive or predominant breastfeeding. Malnutrition increases the risk of diarrhea and associated mortality, and moderate to severe stunting increases the odds of diarrhea-associated mortality. The fraction of such infectious diarrhea deaths that are attributable to nutritional deficiencies varies with the prevalence of deficiencies; the highest attributable fractions are in sub-Saharan Africa, south Asia, and Andean Latin America. The risks are particularly higher with micronutrient malnutrition; in children with vitamin A deficiency, and accounts for 157,000 deaths from diarrhea, measles, and malaria. Zinc deficiency is estimated to cause 116,000 deaths from diarrhea and pneumonia. Table 340-7 summarizes some of the key risk factors associated with childhood diarrhea globally.

The majority of cases of diarrhea resolve within the 1st wk of the illness. A smaller proportion of diarrheal illnesses fail to resolve and persist for longer than 2 wk. Persistent diarrhea is defined as episodes that began acutely but last for 14 or more days. Such episodes account for 3-19% of all diarrheal episodes in children younger than 5 yr of age and up to 50% of all diarrhea-related deaths; persistent diarrhea has a case fatality rate of 60%. Many children (especially infants and toddlers) in developing countries have frequent episodes of acute diarrhea. Although few individual episodes persist beyond 14 days, frequent episodes of acute diarrhea, as well as prolonged diarrhea (lasting between 7-13 days of age), can result in nutritional compromise and can predispose these children to develop persistent diarrhea, protein-calorie malnutrition, and secondary infections.

**CLINICAL MANIFESTATION OF DIARRHEA**

Most of the clinical manifestations and clinical syndromes of diarrhea are related to the infecting pathogen and the dose or inoculum (see Tables 340-1 to 340-3). Additional manifestations depend on the development of complications (e.g., dehydration and electrolyte imbalance).

and the nature of the infecting pathogen (Table 340-8). Usually the ingestion of preformed toxins (e.g., those of *S. aureus*) is associated with the rapid onset of nausea and vomiting within 6 hr, with possible fever, abdominal cramps, and diarrhea within 8-72 hr. Watery diarrhea and abdominal cramps after an 8-16 hr incubation period are associated with enterotoxin-producing *C. perfringens* and *B. cereus*. Abdominal cramps and watery diarrhea after a 16-48 hr incubation period can be associated with noroviruses, several enterotoxin-producing bacteria, *Cryptosporidium*, and *Cyclospora*, and also have been a notable feature of influenza virus H1N1 infections. Several organisms, including *Salmonella*, *Shigella*, *C. jejuni*, *Yersinia enterocolitica*, enteroinvasive or hemorrhagic (Shigatoxin-producing) *E. coli*, and *V. parahaemolyticus*, produce diarrhea that can contain blood as well as fecal leukocytes in association with abdominal cramps, tenesmus, and fever; these features suggest bacterial dysentery and fever (Table 340-8). Bloody diarrhea and abdominal cramps after a 72-120 hr incubation period are associated with infections from *Shigella* and also Shigatoxin-producing *E. coli*, such as *E. coli* O157:H7. Organisms associated with dysentery or hemorrhagic diarrhea can also cause watery diarrhea alone without fever or that precedes a more complicated course that results in dysentery.

Although many of the manifestations of acute gastroenteritis in children are nonspecific, some clinical features can help identify major categories of diarrhea and allow rapid triage for antibiotic or specific dietary therapy (see Tables 340-1 to 340-4). There is considerable overlap in the symptomatology. The positive predictive values for the features of dysentery are very poor; the negative predictability for bacterial pathogens is much better in the absence of signs of dysentery. If warranted and if facilities and resources permit, the etiology can be verified by appropriate laboratory testing.

**COMPlications**

Most of the complications associated with gastroenteritis are related to delays in diagnosis and delays in the institution of appropriate therapy. Without early and appropriate rehydration, many children with acute diarrhea would develop dehydration with associated complications (see Chapter 57). These can be life-threatening in infants and young children. Inappropriate therapy can lead to prolongation of the diarrheal episodes, with consequent malnutrition and complications such as secondary infections and micronutrient deficiencies (iron, zinc, vitamin A). In developing countries and HIV-infected populations, associated bacteremias are well-recognized complications in malnourished children with diarrhea.

Specific pathogens are associated with extraintestinal manifestations and complications. These are not pathognomonic of the infection, nor do they always occur in close temporal association with the diarrheal episode (Table 340-9).

**DIAGNOSIS**

The diagnosis of gastroenteritis is based on clinical recognition, an evaluation of its severity by rapid assessment and by confirmation by appropriate laboratory investigations, if indicated.

### Clinical Evaluation of Diarrhea

The most common manifestations of gastrointestinal tract infection in children are diarrhea, abdominal cramps, and vomiting. Systemic manifestations are varied and associated with a variety of causes. The evaluation of a child with acute diarrhea includes:

- Assessing the degree of dehydration and acidosis and provide rapid resuscitation and rehydration with oral or intravenous fluids as required (Tables 340-10 and 340-11).
- Obtaining appropriate contact, travel, or exposure history. This includes information on exposure to contacts with similar symptoms, intake of contaminated foods or water, child-care center attendance, recent travel of patient or contact with a person who traveled to a diarrhea-endemic area, and use of antimicrobial agents.
- Clinically determining the etiology of diarrhea for institution of prompt antibiotic therapy, if indicated.
- Assessing the degree of dehydration and acidosis and providing rapid resuscitation and rehydration with oral or intravenous fluids as required (Tables 340-10 and 340-11).
- Obtaining appropriate contact, travel, or exposure history. This includes information on exposure to contacts with similar symptoms, intake of contaminated foods or water, child-care center attendance, recent travel of patient or contact with a person who traveled to a diarrhea-endemic area, and use of antimicrobial agents.
- Clinically determining the etiology of diarrhea for institution of prompt antibiotic therapy, if indicated.

Although nausea and vomiting are nonspecific symptoms, they indicate infection in the upper intestine. Fever suggests an inflammatory process but also occurs as a result of dehydration or coinfection (e.g., urinary tract infection, otitis media). Fever is common in patients with inflammatory diarrhea. Severe abdominal pain and tenesmus indicate involvement of the large intestine and rectum. Features such as nausea and vomiting and absent or low-grade fever with mild to moderate periumbilical pain and watery diarrhea indicate small intestine involvement and also reduce the likelihood of a serious bacterial infection.

This clinical approach to the diagnosis and management of diarrhea in young children is a critical component of the Integrated Manage-

high stool output (>10 mL/kg/hr). Ondansetron (oral mucosal absorption preparation) reduces the incidence of emesis, thus permitting more effective oral rehydration and is well established in emergency management of acute gastroenteritis in developed countries.

**Enteral Feeding and Diet Selection**

Continued enteral feeding in diarrhea aids in recovery from the episode, and a continued age-appropriate diet after rehydration is the norm. Although intestinal brush-border surface and luminal enzymes can be affected in children with prolonged diarrhea, there is evidence that satisfactory carbohydrate, protein, and fat absorption can take place on a variety of diets. Once rehydration is complete, food should be reintroduced while oral rehydration is continued to replace ongoing losses from emesis or stools and for maintenance. Breastfeeding or nondiluted regular formula should be resumed as soon as possible. Foods with complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables are also tolerated. Fatty foods or foods high in simple sugars (juices, carbonated sodas)

</table>

*Overly restricted diets should be avoided during acute diarrheal episodes. Breastfed infants should continue to nurse ad libitum even during acute rehydration. Infants too weak to eat can be given milk or formula through a nasogastric tube. Lactose-containing formulas are usually well tolerated. If lactose malabsorption appears clinically substantial, lactose-free formulas can be used. Complex carbohydrates, fresh fruits, lean meats, yogurt, and vegetables are all recommended. Carbonated drinks or commercial juices with a high concentration of simple carbohydrates should be avoided.

---

Figure 340-6 Integrated Management of Childhood Illnesses (IMCI) protocol for the recognition and management of diarrhea in developing countries. ORS, Oral rehydration solution.
Part XVIII • The Digestive System

1872

The Digestive System

Algorithm for managing children with prolonged diarrhea in developing countries.

Among children in low- and middle-income countries, where the dual burden of diarrhea and malnutrition is greatest and where access to proprietary formulas and specialized ingredients is limited, the use of locally available age-appropriate foods should be promoted for the majority of acute diarrhea cases. Lactose intolerance is an important complication in some cases, but even among those children for whom lactose avoidance may be necessary, nutritionally complete diets comprised of locally available ingredients can be used at least as effectively as commercial preparations or specialized ingredients. These same conclusions may also apply to the dietary management of children with persistent diarrhea, but the evidence remains limited.

Zinc Supplementation

Zinc supplementation in children with diarrhea in developing countries leads to reduced duration and severity of diarrhea and could potentially prevent a large proportion of cases from recurring. Zinc administration for diarrhea management can significantly reduce all-cause mortality by 46% and hospital admission by 23%. In addition to improving diarrhea recovery rates, administration of zinc in community settings leads to increased use of ORS and reduction in the inappropriate use of antimicrobials. All children older than 6 mo of age with acute diarrhea in at-risk areas should receive oral zinc (20 mg/
day) in some form for 10-14 days during and continued after diarrhea. The role of zinc in well nourished, zinc replete populations in developed countries is less certain.

Additional Therapies
The use of probiotic nonpathogenic bacteria for prevention and therapy of diarrhea has been successful in some settings although the evidence is inconclusive to recommend their use in all settings. In addition to restoring beneficial intestinal flora, probiotics can enhance host protective immunity such as downregulation of proinflammatory cytokines and upregulation of anti-inflammatory cytokines. A variety of organisms (Lactobacillus, Bifidobacterium) have a good safety record; therapy has not been standardized and the most effective (and safe) organism has not been identified. Saccharomyces boulardii is effective in antibiotic-associated and in C. difficile diarrhea, and there is some evidence that it might prevent diarrhea in daycare centers. Lactobacillus rhamnosus GG is associated with reduced diarrheal duration and severity, which reduction is more evident in cases of childhood rotavirus diarrhea.

Antimotility agents (loperamide) are contraindicated in children with dysentery and probably have no role in the management of acute watery diarrhea in otherwise healthy children. Similarly, antiemetic agents, such as the phenothiazines, are of little value and are associated with potentially serious side effects (lethargy, dystonia, malignant hypopyrexia). Nonetheless, ondansetron is an effective and less-toxic antiemetic agent and as indicated previously, is a useful adjunct to the treatment of vomiting in ambulatory settings with reduced risk of intravenous fluid requirements and hospitalization. Because persistent vomiting can limit oral rehydration therapy, a single sublingual dose of an oral dissolvable tablet of ondansetron (4 mg-11 yr and 8 mg for children older than 11 yr [generally 0.2 mg/kg]) may be given. However, most children do not require specific antiemetic therapy; careful oral rehydration therapy is usually sufficient.

Racemadotril, an enkephalin inhibitor, has inconsistently been shown to reduce stool output in patients with diarrhea. Experience with this drug in children is limited, and for the average child with acute diarrhea it may be unnecessary.

Antibiotic Therapy
Timely antibiotic therapy in select cases of diarrhea related to bacterial infections can reduce the duration and severity of illness and prevent complications (Table 340-12). Although these agents are important to use in specific cases, their widespread and indiscriminate use leads to the development of antimicrobial resistance. Nitazoxanide, an antifungal agent, is effective in the treatment of a wide variety of pathogens, including C. parvum, G. lamblia, E. histolytica, Blastocystis hominis, C. difficile, and rotavirus.

PREVENTION
In many developed countries, diarrhea caused by pathogens such as C. botulinum, E. coli O157:H7, Salmonella, Shigella, V. cholerae, Cryptosporidium, and Cyclospora is a notifiable disease and, thus, contact tracing and source identification is important in preventing outbreaks.

Many developing countries struggle with huge disease burdens of diarrhea where a wider approach to diarrhea prevention may be required. Preventive strategies may be of relevance to both developed and developing countries.

Promotion of Exclusive Breastfeeding
Exclusive breastfeeding (administration of no other fluids or foods for the 1st 6 mo of life) is not common, especially in many developed countries. Exclusive breastfeeding protects very young infants from diarrheal disease through the promotion of passive immunity and through reduction in the intake of potentially contaminated food and water. Breast milk contains all the nutrients needed in early infancy, and when continued during diarrhea, it also diminishes the adverse impact on nutritional status. Exclusive breastfeeding for the 1st 6 mo of life is widely regarded as one of the most effective interventions to reduce the risk of premature childhood mortality and the potential to prevent 12% of all deaths of children younger than 5 yr of age.

Improved Complementary Feeding Practices
There is a strong inverse association between appropriate, safe complementary feeding and mortality in children age 6-11 mo; malnutrition is an independent risk for the frequency and severity of diarrheal illness. Complementary foods should be introduced at 6 mo of age, and breastfeeding should continue for up to 2 yr. Complementary foods in developing countries are generally poor in quality and often are heavily contaminated, thus predisposing to diarrhea. Contamination of complementary foods can be potentially reduced through caregivers’ education and improving home food storage. Improved vitamin A status has been shown to reduce the frequency of severe diarrhea. Vitamin A supplementation reduces all-cause childhood mortality by 25% (95% confidence interval [CI], 12-36%) and diarrhea-specific mortality by 30% (95% CI, 14-42%).

Rotavirus Immunization
Most infants acquire rotavirus diarrhea early in life; an effective rotavirus vaccine would have a major effect on reducing diarrhea mortality in developing countries. In 1998, a quadrivalent Rhesus rotavirus-derived vaccine was licensed in the United States but subsequently withdrawn because of an increased risk of intussusception. Subsequent development and testing of newer rotavirus vaccines have led to their introduction in most developed countries and approval by the WHO in 2009 for widespread use in developing countries. It is now clear that the introduction of these vaccines is associated with a significant reduction in severe diarrhea and associated mortality.

The institution of large-scale rotavirus vaccination programs has led to major reduction in the burden of disease and associated mortality. In an evaluation of large-scale rotavirus vaccine introduction, coverage rate of 74% was achieved in infants younger than 12 mo of age, with 41% reduction (95% CI, 36-47%) in diarrhea-related mortality. In an evaluation of the vaccine in Africa, overall protective efficacy against rotavirus gastroenteritis ranged from 49-61%, with 30% protective efficacy against all-cause severe gastroenteritis in infancy. Vaccine (live virus) associated rotavirus infection has been reported in children with severe combined immunodeficiency disease, but the vaccine has been shown to be safe in HIV-infected populations.

Other vaccines that could potentially reduce the burden of severe diarrhea and mortality in young children are vaccines against cholera, Shigella, and ETEC. Preventive use of cholera vaccines in endemic countries can reduce the risk of developing cholera by 52% (95% CI, 36-65%).

Improved Water and Sanitary Facilities and Promotion of Personal and Domestic Hygiene
Much of the reduction in diarrhea prevalence in the developed world is the result of improvement in standards of hygiene, sanitation, and water supply. Strikingly, an estimated 88% of all diarrheal deaths worldwide can be attributed to unsafe water, inadequate sanitation, and poor hygiene. Improving water quality can reduce the risk of diarrhea by 17%, whereas hand washing with soap and safe excreta disposal reduce the risk of diarrhea by 48% and 36%, respectively. Behavioral change strategies through promotion of handwashing indicate that handwashing promotion and access to soap reduces the burden of diarrhea in developing countries.

Improved Case Management of Diarrhea
Improved management of diarrhea through prompt identification and appropriate therapy significantly reduces diarrhea duration, its nutritional penalty, and risk of death in childhood. Improved management of acute diarrhea is a key factor in reducing the burden of prolonged episodes and persistent diarrhea. The WHO/UNICEF recommendations to use low-osmolality ORS and zinc supplementation for the management of diarrhea, coupled with selective and appropriate use of antibiotics, have the potential to reduce the number of diarrheal
Community-based interventions to diagnose and treat childhood diarrhea through community health workers leads to a significant rise in the unnecessary use of antibiotics for diarrhea by 75%. Significantly increased use of ORS and zinc at household level as well as diarrhea through community health workers leads to a significant rise in deaths among children through Community Case Management and Integrated Management of Childhood Illnesses.

Traveler's diarrhea is a common complication of visitors to developing countries and is caused by a variety of pathogens, in part depending on the season and the region visited (see Table 340-12). Traveler's diarrhea has a high attack rate among travelers from higher-income countries visiting, during the summer, countries in a warmer climate that have a high prevalence of indigenous infectious diarrhea. Traveler's diarrhea can manifest with watery diarrhea or as dysentery. Without treatment, 90% will have resolved within a week and 98% within a month of onset. Some individuals develop more severe diarrhea and become dehydrated or unwell and may experience systemic complications that warrant further attention. Most cases of traveler's diarrhea resolve spontaneously and a simple stool culture may be the only investigation required. For those individuals with ongoing symptoms, further tests should be requested depending on the history and clinical presentation.

**340.1 Traveler’s Diarrhea**

_Zulfiqar Ahmed Bhutta_

Traveler’s diarrhea is a common complication of visitors to developing countries and is caused by a variety of pathogens, in part depending on the season and the region visited (see Table 340-12). Traveler’s diarrhea has a high attack rate among travelers from higher-income countries visiting, during the summer, countries in a warmer climate that have a high prevalence of indigenous infectious diarrhea. Traveler’s diarrhea can manifest with watery diarrhea or as dysentery. Without treatment, 90% will have resolved within a week and 98% within a month of onset. Some individuals develop more severe diarrhea and become dehydrated or unwell and may experience systemic complications that warrant further attention. Most cases of traveler’s diarrhea resolve spontaneously and a simple stool culture may be the only investigation required. For those individuals with ongoing symptoms, further tests should be requested depending on the history and clinical presentation.

**TREATMENT**

Traveler’s diarrhea is often self-limiting but requires particular attention to avoid dehydration. For infants and children, rehydration, as

discussed in Chapter 340, is appropriate, followed by a standard diet. Adolescents and adults should increase their intake of electrolyte-rich fluids. Kaolin-pectin, anticholinergic agents, *Lactobacillus*, and bismuth salicylate have not been effective therapies. Loperamide, an antimotility and antisecretory agent, reduces the number of stools in older children with watery diarrhea and improves outcomes when used in combination with antibiotics in traveler’s diarrhea. However, loperamide should be used with great caution or not at all in febrile or toxic patients with dysentery and in those with bloody diarrhea. Antibiotics, with or without loperamide, can also reduce the number of unformed stools. Short-duration (3 days) therapy with fluoroquinolones, trimethoprim-sulfamethoxazole, azithromycin, or rifaximin is effective; the choice of antibiotic depends on the age of the patient, the potential organism, and the organism’s local resistance patterns. However, antibiotics often have a negative risk-benefit ratio when weighing potential side effects vs treatment need for a short-lasting and self-limiting disease such as traveler’s diarrhea. Azithromycin has several advantages over other antibiotics. It is taken only once (1,000 mg), the rate of antimicrobial resistance is low, and it has a good safety profile. Furthermore, in contrast to rifaximin, it can be used in severe cases of diarrhea with fever or bloody stools and can even be administered in children. Optionally, azithromycin can be combined with antimotility medications such as loperamide. Travelers should be reminded that diarrhea can be a symptom of other severe diseases, such as malaria. Therefore, if diarrhea persists or additional symptoms such as fever occur, travelers should seek medical advice. For up-to-date information on local pathogens and resistant patterns, see www.cdc.gov/travel.

**PREVENTION**

Travelers should drink bottled or canned beverages or boiled water. They should avoid ice, salads, and fruit they did not peel themselves. Food should be eaten hot, if possible. Raw or poorly cooked seafood is a risk, as is eating in a restaurant rather than a private home. Swimming pools and other recreational water sites can also be contaminated.

Chemoprophylaxis is not routinely recommended for previously healthy children or adults. Nonetheless, travelers should bring azithromycin (younger than 16 yr of age) or ciprofloxacin (older than 16 yr of age) and begin antimicrobial therapy if diarrhea develops.

Bibliography
DEFINITION AND EPIDEMIOLOGY

Chronic diarrhea is defined as stool volume of more than 10 g/kg/day in toddlers/infants and greater than 200 g/day in older children that lasts for 14 days or more. In practice, this usually means having loose or watery stools more than 3 times a day. *Awakening at night to pass stool is often a sign of an organic cause of diarrhea.* The epidemiology has 2 distinct patterns. In developing countries, chronic diarrhea is, in many cases, the result of an intestinal infection that persists longer than expected. This syndrome is often defined as *protracted diarrhea,* but there is no clear distinction between protracted and chronic diarrhea. In countries with higher socioeconomic conditions, chronic diarrhea is less frequent and the etiology often varies with age. The outcome of diarrhea depends on the cause and ranges from benign, self-limited conditions, such as toddler’s diarrhea, to severe congenital diseases, such as microvillus inclusion disease, that may lead to progressive intestinal failure.

**PATHOPHYSIOLOGY**

The mechanisms of diarrhea are generally divided into secretory and osmotic, but often diarrhea is a combination of both mechanisms. In addition, inflammation and motility disorders may contribute to diarrhea. Secretory diarrhea is usually associated with large volumes of watery stools and persists when oral feeding is withdrawn. Osmotic diarrhea is dependent on oral feeding, and stool volumes are usually not as massive as in secretory diarrhea (Fig. 341-1).

**Secretory diarrhea** is characterized by active electrolyte and water fluxes toward the intestinal lumen, resulting from either the inhibition of neutral NaCl absorption in villous enterocytes or an increase in electrogenic chloride secretion in secretory crypt cells as a result of the opening of the cystic fibrosis transmembrane regulator (CFTR) chloride channel or both. The result is more secretion from the crypts than absorption in the villous that persists during fasting. The other components of the enterocyte ion secretory machinery are (1) the Na-K-2Cl cotransporter for the electroneutral chloride entrance into the enterocyte; (2) the Na-K pump, which decreases the intracellular Na concentration, determining the driving gradient for further Na influx; and (3) the K selective channel, that enables K, once it has entered the cell together with Na, to return to the extracellular fluid.

Electrogenic secretion is induced by an increase of intracellular concentration of cyclic adenosine monophosphate, cyclic guanosine monophosphate, or calcium in response to microbial enterotoxins, or to endogenous endocrine or nonendocrine moieties, including inflammatory cytokines. Another mechanism of secretory diarrhea is the inhibition of the electroneutral NaCl-coupled pathway that involves the Na/H and the Cl/HCO exchangers. Defects in the genes of the Na/H and the Cl/HCO exchangers are responsible for congenital Na and Cl diarrhea, respectively.

**Osmotic diarrhea** is caused by nonabsorbed nutrients in the intestinal lumen as a result of 1 or more of the following mechanisms: (1) intestinal damage (e.g., enteric infection); (2) reduced absorptive surface area (e.g., active celiac disease); (3) defective digestive enzyme or nutrient carrier (e.g., lactase deficiency); (4) decreased intestinal transit time (e.g., functional diarrhea); and (5) nutrient overload, exceeding the digestive capacity (e.g., overfeeding, sorbitol in fruit juice). Whatever the mechanism, the osmotic force generated by nonabsorbed solutes drives water into the intestinal lumen. A very common
example of osmotic diarrhea is lactose intolerance. Lactose, if not absorbed in the small intestine, reaches the colon, where it is fermented to short-chain organic acids, releasing hydrogen that is detected in the lactose breath test, and generating an osmotic overload. In many children chronic diarrhea may be caused by multiple mechanisms.

### ETIOLOGY

**Enteric infections** are by far the most frequent cause of chronic diarrhea, both in developing and industrialized countries but, outcomes are often very different. In the former, comorbid conditions, such as HIV/AIDS, malaria, or tuberculosis, result in malnutrition that impairs the child’s immune response, thereby potentiating the likelihood of prolonging diarrhea or acquiring another enteric infection. In children with HIV/AIDS, the viral infection itself impairs immune function and may trigger a vicious circle with malnutrition. Sequential infections with the same or different pathogens may also be responsible for chronic diarrhea.

In developing countries, enteropathogenic *Escherichia coli* and *Giardia lamblia* have been implicated in chronic diarrhea, whereas, in developed countries, chronic infectious diarrhea usually runs a more benign course and the etiology is often viral, with a major role of rotavirus and norovirus (*Table 341-1*). Opportunistic microorganisms induce diarrhea exclusively, more severely or for more prolonged periods, in specific populations, such as immunocompromised children. Specific agents cause chronic diarrhea or exacerbate diarrhea in many chronic diseases. *Clostridium difficile* or *cytomegalovirus* act as opportunistic agents in oncologic patients as well as in patients with inflammatory bowel diseases. *Cryptosporidium* may induce severe and protracted diarrhea in AIDS patients.

In small intestinal bacterial overgrowth, diarrhea may be the result of either a direct interaction between the microorganism and the enterocyte or the consequence of deconjugation and dehydroxylation of bile salts, and hydroxylation of fatty acids due to an increased proliferation of bacteria in the proximal intestine. Postenteritis diarrhea syndrome is a clinicopathologic condition in which small intestinal mucosal damage persists after acute gastroenteritis. Sensitization to food antigens, secondary disaccharidase deficiency, persistent infections, reinfection with an enteric pathogen, or side effects of medications may be responsible for increasing postenteritis diarrhea syndrome, thought to be related to perturbations of the intestinal microbiome. Functional diarrhea which may be related to the pathogenesis of irritable bowel syndrome may be caused by complications of an acute gastroenteritis. Noninfectious chronic diarrhea is the manifestation of a broad number of heterogeneous conditions that vary with the age of the patient (*Table 341-2*; see also Table 336-5).

*More frequent in industrialized than in developing countries as agent of chronic diarrhea.

A reduction of intestinal absorptive surface is responsible for diarrhea in celiac disease, a genetically determined permanent gluten intolerance that affects as many as 1 in 100 individuals, depending on geographic origin. In the genetically susceptible host, gliadin, the major protein of gluten, reacts with the immune system to cause villous atrophy. The reduction of functional absorptive surface area is reversible upon restriction of gluten from the diet. Celiac disease presents with more severe intestinal symptoms in younger children. **Allergy to cow’s milk protein** and other food proteins also may present during infancy with chronic diarrhea. Eosinophilic gastroenteritis is characterized by eosinophilic infiltration of the intestinal wall and is strongly associated with atopy. However, whereas diarrhea in food allergy responds to withdrawal of the responsible food, this does not always occur in eosinophilic gastroenteritis, in which immune suppression may be needed.

Lactose intolerance or carbohydrate malabsorption may be caused by a brush-border enzyme defect in lactase, sucrose-isomaltase, or to a defect in the sodium/glucose cotransporter protein (SGLT1) that is transcribed from the SLCA1 gene causing congenital glucose-galactose malabsorption. The result of these genetic mutations is chronic diarrhea. More commonly, lactose intolerance is secondary to lactase deficiency caused by intestinal mucosal damage. Depending on ethnicity, a progressive, age-related, loss of lactase activity may begin around age 7 yr and affects approximately 80% of the nonwhite population, and acquired hypolactasia may be responsible for chronic diarrhea in older children receiving cow’s milk (adult-type lactase deficiency).

In older children and adolescents, **inflammatory bowel diseases**, including Crohn disease, ulcerative colitis, and inflammatory bowel disease–undetermined, cause chronic diarrhea that is often associated with abdominal pain, elevated inflammatory markers, and increased concentrations of fecal calprotectin or lactoferrin (see Chapter 336). The age of onset of inflammatory bowel disease is broad, with rare cases described in the 1st few mo of life, but the peak incidence in childhood occurring in adolescence. The severity of the symptoms is highly variable with a pattern characterised by long periods of well-being followed by exacerbations. Growth retardation and delays in sexual maturation may precede the onset of gastrointestinal symptoms by up to 18 mo.

Chronic diarrhea may be the manifestation of malabsorption caused by exocrine **pancreatic disorders**. In most patients with cystic fibrosis, exocrine pancreatic insufficiency results in steatorrhea and protein malabsorption. In Shwachman–Diamond syndrome, exocrine pancreatic hypoplasia may be associated with neutropenia, bone changes, and intestinal protein-losing enteropathy. Specific isolated pancreatic enzyme defects, such as lipase deficiency, result in fat and/or protein malabsorption. Familial pancreatitis, associated with a mutation in the trypsinogen gene, may be associated with exocrine pancreatic insufficiency and chronic diarrhea. Mutations in CFTR, CTRC, PRSS1, SPINK 1, and SPINK 5 are all associated with hereditary pancreatitis.

Liver disorders may lead to a reduction in the bile salts pool resulting in fat malabsorption. Bile acid loss may be associated with diseases affecting the terminal ileum, such as Crohn disease, or following ileal resection. In primary bile acid malabsorption, neonates and young infants present with chronic diarrhea and fat malabsorption caused by mutations of ileal bile transporter.

The most benign etiology of chronic diarrhea is nonspecific diarrhea that encompasses functional diarrhea (or toddler’s diarrhea) in children younger than 4 yr of age and irritable bowel syndrome in those 5 yr of age and older. The diseases fall under the umbrella of functional disorders, in that in older children abdominal pain is often associated with diarrhea alternating with constipation and growth and weight gain are normal.

Diarrhea may be the result from an **excessive intake of fluid and carbohydrate**. If the child’s fluid intake were >150 mL/kg/24 hr, fluid intake should be reduced not to exceed 90 mL/kg/24 hr. The child is often irritable in the 1st days of the fluid restriction; however, persistence results in a decrease in the stool frequency and volume. If the dietary history suggests that the child is ingesting significant amounts of fruit juice, especially apple juice, then the consumption of juice

should be decreased. Sorbitol, which is a nonabsorbable sugar, is found in apple, pear, and prune juices, and often causes diarrhea in toddlers. Moreover, apple and pear juices contain higher amounts of fructose than glucose, a feature postulated to cause diarrhea in toddlers. In older children, irritable bowel syndrome is often associated with abdominal pain and may be related to anxiety, depression, and other psychologic disturbances.

The most severe etiology of chronic diarrhea includes a number of heterogeneous congenital conditions leading to syndromes related to intractable diarrhea. This is often the result of a permanent defect in the structure or function of the enterocyte, leading to progressive, potentially irreversible intestinal failure. The main etiologies of intractable diarrhea include structural enterocyte defects, disorders of intestinal motility, immune-based disorders, short gut syndrome, and disorders without demonstrable abnormalities.

**Structural enterocyte defects** are caused by specific molecular defects responsible for early onset, severe diarrhea. In microvillus inclusion disease, microvilli are sequestered in vacuoles as a consequence of autophagocytosis because of a defect in protein trafficking disrupting enterocyte polarity (Fig. 341-2). Intestinal epithelial dysplasia (or tufting enteropathy) is caused by focal crowding of enterocytes that produce epithelial abnormalities resembling tufts (tears). Abnormal deposition of laminin and heparan sulfate proteoglycan on the basement membrane has been detected in intestinal epithelia. An abnormal intestinal distribution of αβ1 and αβ4 integrins is implicated in tufting enteropathy. These ubiquitous proteins are involved in cell–cell and cell–matrix interactions, and play a crucial role in cell development and differentiation.

Electrolyte transport defects are a subgroup of structural enterocyte defects that include congenital chloride diarrhea, in which a mutation in the solute carrier family 26 member 3 gene (SLC26A3) leads to severe intestinal Cl− malabsorption from a defect in or absence of the Cl−/HCO3− exchanger. The consequent defect in bicarbonate secretion leads to metabolic alkalosis and acidification of the intestinal content, with further inhibition of Na+/H+ exchanger-dependent Na+ absorption. Patients with congenital sodium diarrhea show similar clinical features, because of a defective Na+/H+ exchanger in the small and large intestine, leading to massive Na+ fecal loss and severe acidosis. Familial diarrhea syndrome caused by a mutation guanylate cyclase-C is characterized by abdominal pain, dysmotility, and inflammation coupled with mild secretory diarrhea.

**Disorders of intestinal motility** include abnormal development and function of the enteric nervous system, such as in Hirschsprung disease and chronic idiopathic intestinal pseudo-obstruction (which encompass both the neurogenic and the myogenic forms). Other motility disorders may be secondary to extraintestinal disorders, such as in hyperthyroidism and scleroderma. Motility disorders are associated with either constipation or diarrhea or both, with the former usually dominating the clinical picture.

**Autoimmune processes** may target the intestinal epithelium, alone or in association with extraintestinal symptoms. Autoimmune enteropathy is associated with the production of antienterocyte and antiglobet cell antibodies, primarily immunoglobulin A, but also immunoglobulin G, directed against components of the enterocyte brush-border or cytoplasm and by a cell-mediated autoimmune response with mucosal T-cell activation. An X-linked
B C diarrhea.

The villous enterocyte lack brush-border microvilli, whereas their apical cytoplasm contains a microvillus inclusion (PAS) staining highlights abundant PAS-positive material detected in the same enterocyte.

bloating, vomiting, diarrhea, and hypoglycemia. Continued ingestion hereditary fructose intolerance may have nausea, abdominal pain/liver and is involved in the metabolism of fructose. Individuals with fructose intolerance is associated with mutations in the gene that encodes for the aldolase B enzyme that is found primarily in the small intestine may be insufficient to carry on its digestive-absorptive functions. Rarely, a child may be born with a congenitally short small bowel resulting in delayed growth. In rare cases of severe chronic diarrhea, the gastrointestinal symptoms may be the initial manifestation of mitochondrial disease, carbohydrate deficient glycoproteins, or a primary immune deficiency. Multiple food protein hypersensitivity also is included in the list of causes of protracted diarrhea syndrome. The disease is believed to be the result of a reaction against specific proteins contained in foods. Diarrhea often resolves with fasting or when an amino-acid–based formula is started. Although most children with food intolerance in infancy are eventually able to resume a regular diet, some require restrictions throughout their lives. When the cause of the diarrhea remains undetermined and the clinical course is inconsistent with organic disorders, factitious disorder by proxy should be considered.

**GENETIC AND MOLECULAR BASIS OF THE PROTRACTED DIARRHEA SYNDROME**

The genetic and molecular basis of many causes of protracted diarrhea have been identified recently and a new classification of congenital diarrheal disorders (CDDs) has been proposed (Table 341-3). CDDs are a group of rare, but severe enteropathies, with a similar clinical presentation despite a different outcome. However, diarrhea is the result of structural and functional abnormalities resulting in either secretory or osmotic diarrhea. Often diarrhea presents at birth or shortly thereafter, but in milder forms diarrhea may go unrecognized for years. CDDs are rare diseases, however in most specific disorders the specific genetic defect and transmission are known. Hereditary fructose intolerance is associated with mutations in the ASDOB gene that encodes for the aldolase B enzyme that is found primarily in the liver and is involved in the metabolism of fructose. Individuals with hereditary fructose intolerance may have nausea, abdominal pain/bloating, vomiting, diarrhea, and hypoglycemia. Continued ingestion of fructose results in hepatomegaly and eventually cirrhosis. The incidence of hereditary fructose intolerance is estimated to be 1 in 20,000-30,000. In contrast, fructose malabsorption is common in Western countries with estimates as high as 40% of the population. These individuals cannot absorb fructose and often develop bloating, abdominal pain, diarrhea, and flatulence. They do not have liver disease.

The incidence of other genetic disorders associated with CDD ranges from 1 in 2,500 for cystic fibrosis, 1 in 5,000 for sucrase-isomaltase deficiency, 1 in 60,000 for congenital lactase deficiency, to 1 in 400,000 to trichohepatoenteric syndrome. For most CDDs, such as polyendocrinopathy, X-linked (IPEX) syndrome, or autoimmune polyglandular syndrome type 1, the clinical application of exome

AD, autosomal dominant; AR, autosomal recessive.
sequencing is likely to increase identification of more patients with these rare causes of chronic diarrhea.

Selected CDDs are more frequent in ethnic groups where consanguineous marriages are common, or in some geographic areas because of founder effects. For example, congenital lactase deficiency is more common in Finland; lysinuric protein intolerance has a higher incidence either in Finland and in Japan because of founder effect, and a specific mutation is typically found in each of the 2 ethnic groups. A defect in the DGAT1 gene was identified using whole-exome sequencing in an Ashkenazi Jewish family and associated with the early onset of vomiting and nonbloody diarrhea with protein-losing enteropathy.

Most cases of protracted diarrhea syndrome are not easily treated. The natural history of protracted diarrhea is related to the primary intestinal disease and the specific defect in nutrient absorption. Treatment is more favorable for motility disorders and autoimmune enteropathy than for structural enterocyte defects. Children with motility disorders may have persistent symptoms, but they are rarely fatal; whereas children with structural enterocyte defects have a more severe course, poorer prognosis, and are more likely to be candidates for intestinal transplantation (see Chapter 339). Some late-onset CDDs may be relatively mild and are recognized only later in life.

### EVALUATION OF PATIENTS

Because of the spectrum of etiologies, the medical approach should be based on diagnostic algorithms that begin with assessment for infectious causes, and then consider the age of the child, growth, and clinical and epidemiologic factors. Early onset may suggest a congenital or severe condition. In later infancy and up to 2 yr of age, infections and allergies are more common; inflammatory diseases are more frequent in older children and adolescents. Celiac disease and chronic nonspecific diarrhea should always be considered independently of age because of their relatively high frequency at all ages.

Specific clues in the family and personal history may provide useful indications, suggesting a congenital, allergic or inflammatory etiology. A history of polyhydramnios is consistent with congenital chloride-sodium diarrhea, or cystic fibrosis. An acute onset of diarrhea that runs a protracted course suggests post-enteritis diarrhea or small intestinal overgrowth or the onset of chronic nonspecific diarrhea (toddler's diarrhea). In children, with chronic nonspecific diarrhea there is often a history of an acute gastroenteritis. The association of diarrhea with specific foods may indicate a nutrient basis, such as intolerance to selected nutrients (fructose). Anthropometric evaluation is essential to understand if diarrhea has affected weight gain and growth. The amount of weight loss over time provides an estimate of the severity of diarrhea. Normal weight and growth strongly support functional diarrhea that may respond to simple dietary management.

Initial clinical examination should include the evaluation of general and nutritional status. Dehydration, marasmus, or kwashiorkor require prompt supportive interventions to stabilize the patient. Nutritional evaluation should start with the evaluation of the weight and height curves, and of the weight-for-height index to determine the impact of diarrhea on growth. Weight is generally impaired before height, but with time, linear growth also becomes affected, and both parameters may be equally abnormal in the long-term. Assessment of nutritional status includes a dietary history and biochemical and nutritional investigations. Caloric intake should be quantitatively determined and the relationship between weight modifications and energy intake should be carefully considered.

Biochemical markers may assist in grading malnutrition (Table 341-4) as the half-life of serum proteins may distinguish between short- and long-term malnutrition. Assessment of body composition may be performed by measuring mid-arm circumference and triceps skinfold thickness or, more accurately, by bioelectrical impedance analysis or dual-emission x-ray absorptiometry scans. Evaluation of micronutrient concentrations should always be considered. Zinc, magnesium, vitamin A, and folate deficiency are associated with chronic diarrhea and should be provided if needed.

Diagnosis of functional diarrhea is based on clinical assessment using established age-related criteria. It should be noted that a child with functional diarrhea may be inappropriately “treated” with a diluted hypocaloric diet in an effort to reduce the diarrhea, resulting in impaired growth.

The search for an etiology may be based on the relevant causes of diarrhea for the age of the child. Continued diarrhea with fasting or fecal electrolyte concentrations discriminate between secretory and osmotic diarrhea. Associated symptoms and selected investigations provide important diagnostic clues. Signs of general inflammation such as fever, mucoid or bloody stools, and abdominal pain may suggest inflammatory bowel disease. The presence of eczema or asthma is associated with an allergic disorder, whereas specific extraintestinal manifestations (arthritis, diabetes, thrombocytopenia, etc.) may suggest an autoimmune disease. Specific skin lesions may be suggestive of acrodermatitis enteropathica that might respond to zinc replacement. Typical facial abnormalities and woolly hair are associated with phenotypic diarrhea (see Fig. 341-3).

### INVESTIGATIONS

Microbiologic investigation should include a thorough list of intestinal bacterial, viral, and protozoan pathogens. Proximal intestinal bacterial overgrowth may be determined using the hydrogen breath test, after an oral glucose or lactulose load, but either substrate may give false results.

Initial investigations of a child with chronic diarrhea should always include an assessment of intestinal inflammation using fecal calprotectin or lactoferrin, and serology for celiac disease (see Chapter 338.2). The role of a mucosal biopsy is determined by the noninvasive diagnostic evaluation in consultation with a pediatric gastroenterologist.

Noninvasive assessment of digestive-absorptive function and of intestinal inflammation plays a key role in the diagnostic work-up (Table 341-5). Abnormalities in the digestive-absorptive function tests suggest small bowel involvement, whereas intestinal inflammation, as demonstrated by increased fecal calprotectin or lactoferrin, supports colitis. Histology is important in establishing mucosal involvement, noting changes in the epithelial cells, or in identifying specific
intracellular inclusion bodies caused by pathogens, such as cytomegalovirus, or the presence of parasites. Electron microscopy is essential to detect subcellular structural abnormalities such as microvillous inclusion disease. Immunohistochemistry allows the study of mucosal immunity as well as of other cell types (smooth muscle cells and enteric neuronal cells).

Imaging has a major role in the diagnostic approach. Abdominal ultrasound may help in detecting liver and pancreatic abnormalities or an increase in distal ileal wall thickness that suggests inflammatory bowel disease. A preliminary plain abdominal x-ray is useful for detection of abdominal distention, suggestive of intestinal obstruction, or increased retention of colonic feces. Intramural or portal gas may be seen in necrotizing enterocolitis or intussusception. Structural abnormalities such as diverticula, malrotation, stenosis, blind loop, inflammatory bowel disease, as well as motility disorders, may be investigated through a barium meal and a small bowel follow-through. Capsule endoscopy allows the exploration of the entire intestinal tract searching for structural changes, inflammation or bleeding and the new SmartPill measures pressure, pH, and temperature as it moves through the gastrointestinal tract, assessing motility.

Specific investigations should be carried out for specific diagnostic indications. Prick and patch test may support a diagnosis of food allergy. However, elimination diet with withdrawal of the suspected harmful food from the diet and subsequent challenge is the most reliable strategy by which to establish a diagnosis. Bile malabsorption may be explored by the retention of the bile acid analog $^{75}$Se-homocholic acid-taurine ($^{75}$SeHCAT) in the enterohepatic circulation. A scintigraphic examination, with radio-labeled octreotide is indicated in suspected APUD cell neoplastic proliferation. In other diseases, specific imaging techniques such as computed tomography, or nuclear magnetic resonance endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography may have important diagnostic value.

Once infectious agents have been excluded and nutritional assessment performed, a stepwise approach to the child with chronic diarrhea may be applied. The main causes of chronic diarrhea should be investigated, based on the features of the diarrhea and the specific nutrient(s) that is (are) affected. The use of whole-exome sequencing is of benefit in children suspected of having mendelian-related causes of chronic diarrhea. A step-by-step diagnostic approach is important to minimize the unnecessary use of invasive procedures as well as the cost, while optimizing the yield of the diagnostic work-up (Table 341-6).

### TREATMENT

Chronic diarrhea associated with impaired nutritional status should always be considered a serious disease, and therapy should be started promptly. Treatment includes general supportive measures, nutritional rehabilitation, elimination diet, and medications. The latter include therapies for specific etiologies as well as interventions aimed at countering fluid secretion and/or promoting restoration of disrupted intestinal epithelium. Because death in most instances is caused by dehydration, replacement of fluid and electrolyte losses is the most important early intervention.

Nutritional rehabilitation is often essential and is based on clinical and biochemical assessment. Potentially harmful nutrients must be identified and avoided. In moderate to severe malnutrition, caloric intake may be progressively increased to 50% or more above the recommended dietary allowances. The intestinal absorptive capacity should be monitored by digestive function tests. In children with steatorrhea, medium-chain triglycerides may be the main source of lipids. A lactose-free diet should be started in all children with chronic diarrhea and is recommended by the World Health Organization. Lactose is generally replaced by maltodextrin or a combination of complex carbohydrates. A sucrose-free formula is indicated in sucrase-isomaltase deficiency. Semielemental or elemental diets have the dual purpose of overcoming food intolerance, which may be the primary cause of chronic diarrhea, particularly in infancy and early childhood, and facilitating nutrient absorption. The sequence of elimination should begin from less to more restricted diets, that is, cow's milk protein hydrolysate to amino-acid–based formulas, depending on the child's situation. In severely compromised infants, it may be prudent to start with amino-acid–based feeding.

When oral nutrition is not feasible or fails, enteral or parenteral nutrition should be considered. Enteral nutrition may be performed via nasogastric or gastrostomy tube and is indicated in a child who is not able to be fed orally, either because of inability to tolerate nutrient requirements or because of extreme weakness. Continuous enteral nutrition is effective in children with a compromised absorptive capacity, such as short bowel syndrome where the remaining mucosal surface is intact. In extreme wasting, enteral nutrition may not be tolerated and parenteral nutrition is required.

Micronutrient and vitamin supplementation are part of nutritional rehabilitation, especially in malnourished children in developing countries. Zinc supplementation is important in both prevention and therapy of chronic diarrhea, since it promotes ion absorption, restores...
epithelial proliferation, and stimulates immune response. Nutritional rehabilitation has a general beneficial effect on the patient’s general condition, intestinal function, and immune response.

Functional diarrhea in children may benefit from a diet based on the “4 F” principles (reduce fructose and fluids, increase fat and fiber). Probiotics have been used with some success as adjunctive therapy based on the evidence that changes in intestinal microflora might be beneficial in several other intestinal diseases.

Pharmacologic therapy includes antiinfectious drugs, immune suppressants, and drugs that may inhibit fluid loss and promote cell growth. If a bacterial agent is detected, specific antibiotics should be prescribed. Empiric antibiotic therapy may be used in children with either small bowel bacterial overgrowth or with suspected infectious diarrhea. Table 341-7 summarizes the treatment of postinfectious persistent diarrhea. Immune suppression should be considered in selected conditions such as autoimmune enteropathy.

Treatment may be also directed at modifying specific pathophysiological processes. Secretion of ions may be reduced by proabsorptive agents, such as the enkephalinase inhibitor racecadotril. In diarrhea caused by neuroendocrine tumors, microvillus inclusion disease and enterotoxin-induced severe diarrhea, a trial of somatostatin analog octreotide may be considered. Zinc promotes both enterocyte growth and ion absorption and may be effective when intestinal atrophy and ion secretion are associated. However, when therapeutic attempts have failed, the only option to avoid intestinal failure may be parenteral nutrition or eventually intestinal transplantation.

Diarrhea from Neuroendocrine Tumors
Helen Spoudeas and David Branski

Rare tumors of the neuroendocrine cells of the gastroenteropancreatic axis and adrenal and extraadrenal sites derive from the APUD system. They are characterized by an excessive production of 1 or several peptides, which, when released into the circulation, exert their endocrine effects and can be measured by radioimmunologic methods (in the plasma or as their urinary metabolites) and hence act as tumor markers.

In clinically functioning tumors, the hypersecretion causes a recognizable syndrome that can include watery diarrhea. Though rare, neuroendocrine tumor (NET) should be considered a potential cause in patients with a particularly severe or chronic course (resulting in electrolyte and fluid depletion), associated flushing, palpitations, or bronchospasm, or a positive family history of multiple endocrine neoplasia 1 or 2 syndromes (Table 341-8).

Depending on the tumor type, the peptide marker(s) in the plasma and/or the 24-hr urinary metabolite(s) measured (on 2 occasions), form the basis of the biochemical diagnosis, the prognosis (tumor load) and treatment monitoring. Baseline tests should include plasma chromogranin A and urinary 5-hydroxyindoloacetic acid, other specific biochemistry being guided by the suspected syndrome (see Table 341-8). Carcinoid tumors are gastroenteropancreatic NETs, typically of the midgut (rather than fore- or hindgut), which may cause flushing and bronchospasm in addition to diarrhea and which, because of their portal drainage, are the most prone to late presentation and malignancy. Localization of any NET is best achieved with a multimodality approach at a center of excellence. Thus whole-body CT, MRI, and somatostatin receptor scintigraphy may be required (because nearly all NETs express membrane receptors for small peptides, e.g., somatostatin), with gallium-68 positron emission tomography/CT recommended for detecting an unknown primary. Long-acting somatostatin analogs might also have a role in palliation.

Tumor resection is the treatment of choice but is potentially hazardous and can precipitate life-threatening adrenergic crises; it should only be undertaken by an endocrine surgeon with experience under carefully controlled medical and anesthetic conditions and in conjunction with an endocrinologist. Tumor histochemistry will confirm the NET type and classification of NETs should be based on the World Health Organization 2010 Union for International Cancer Control TNM criteria (7th edition). This diagnosis in a child should prompt a genetic referral to exclude a tumor predisposition syndrome in which the child is the index case and tumor registration. Management and follow-up is multidisciplinary and should be undertaken in an age-appropriate setting with access to adult specialists with expertise in these rare conditions.

*Adapted from Spoudeas HA, editor: Paediatric endocrine tumours. A multidisciplinary consensus statement of best practice from a working group convened under the auspices of the British Society of Paediatric Endocrinology and Diabetes (BSPED) and the United Kingdom Children’s Cancer Study Group (UKCCSG), Crawley, West Sussex, 2005, Novo Nordisk.*
Recurrent abdominal pain in children was defined as at least 3 episodes of pain over at least 3 mo that interfered with function. In many situations the term recurrent abdominal pain was used synonymously with functional abdominal pain. Other terms, such as chronic abdominal pain, nonorganic abdominal pain, and psychogenic abdominal pain, that were also used for describing abdominal pain in children, led to clinical confusion. The American Academy of Pediatrics Subcommittee on Chronic Abdominal Pain and the North American Society for Pediatric Gastroenterology Hepatology and Nutrition Committee on Abdominal Pain suggested that the term recurrent abdominal pain no longer be used. Table 342-1 outlines the recommended clinical definitions for long-lasting intermittent or constant abdominal pain by the same committees.

Chronic abdominal pain can be organic or nonorganic, depending on whether a specific etiology is identified. Nonorganic abdominal pain or functional abdominal pain refers to pain without evidence of anatomic, inflammatory, metabolic, or neoplastic abnormalities. Functional gastrointestinal disorders (FGIDs) are a group of gastrointestinal (GI) disorders that include variable combinations of chronic or recurrent GI symptoms not explained by structural or biochemical abnormalities. The Rome Committee updates and modifies the information on FGIDs for clinical and research purposes. The Rome III process had 2 pediatric subcommittees based on age range: Neonate/Toddler (0-4 yr) and Child/Adolescent (4-18 yr). The Child/Adolescent committee categorized abdominal pain–related FGIDs under Category H2 (Table 342-2). Table 342-3 defines the Rome III criteria for the diagnosis of Childhood Functional Abdominal Pain (category H2d) and the Childhood Functional Abdominal Pain Syndrome (category H2d1).

The exact incidence and prevalence of chronic abdominal pain is not known. There are reports of chronic abdominal pain affecting 9-15% of children. There are also reports that 13% of middle school and 17% of high school children have weekly complaints of abdominal pain.

### Table 342-3 Rome III Criteria for Childhood Functional Abdominal Pain H2d and Childhood Functional Abdominal Pain Syndrome H2d1

**H2d. CHILDHOOD FUNCTIONAL ABDOMINAL PAIN**

Diagnostic criteria* must include all of the following:

- Episodic or continuous abdominal pain
- Insufficient criteria for other functional gastrointestinal disorders
- No evidence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the subject’s symptoms

**H2d1. CHILDHOOD FUNCTIONAL ABDOMINAL PAIN SYNDROME**

Diagnostic criteria* must satisfy criteria for childhood functional abdominal pain and have at least 25% of the time one or more of the following:

- Some loss of daily function
- Additional somatic symptoms such as headache, limb pain, or difficulty sleeping

*Criteria fulfilled at least once per week for ≥2 mo prior to diagnosis.

Adapted from Rome Foundation: Rome III disorders and criteria. http://www.romecriteria.org/criteria/
PATHOPHYSIOLOGY
The symptoms of FGIDs may be the result of dysfunctions of the intestinal sensory and motor systems. The pathophysiology of functional abdominal pain is complex and not fully understood. Visceral hypersensitivity and motility disturbances are thought to be involved in functional abdominal pain. The traditional concept that motility disorders alone have an important role in functional pain has not been confirmed. It is believed that visceral hypersensitivity leading to abnormal bowel sensitivity to stimuli (physiologic, psychologic, noxious) might have a more dominant role in functional abdominal pain. Visceral hypersensitivity could be the result of abnormal interpretation of normal signals by the brain or aberrant signals sent to the brain or a combination. Intestinal pain receptors respond to mechanica and/or chemical stimuli. The visceral receptors can respond to both mechanical and chemical stimuli, but the mucosal receptors are primarily stimulated by chemical stimuli.

The viscera are innervated by dual set of nerves (vagal and splanchnic spinal nerves or pelvic and splanchnic spinal nerves). The spinal afferents carry impulses to the spinal cord. The dorsal horn of the spinal cord regulates conduction of impulses from peripheral nociceptive receptors to the spinal cord and brain, and the pain experience is further influenced by cognitive and emotional centers. Chronic peripheral nervous system pain can produce increased neural activity in higher central nervous system centers, leading to perpetuation of pain. Psychosocial stress can affect pain intensity and quality through these mechanisms. The child's response to pain can be influenced by stress, personality type, and the reinforcement of illness behavior within the family. The autonomic and enteric nervous systems can overlie the initiation, perception, and perpetuation of pain.

A normal functioning enteric nervous system (ENS) is important for coordination of intestinal motility, secretion, and blood flow. Abnormalities of the ENS may be an underlying factor for functional abdominal pain. Inflammation of the intestine and its role in the pathogenesis of functional abdominal pain could be a result of the effects of the inflammatory mediators and cytokines (released by the various inflammatory cells) on the ENS. The dysregulation in the brain–gut interactions can also lead to functional abdominal pain. The role of certain triggers for pain, such as lactose, sorbitol, fructose, bile acids, or fatty acids, could be a result of the altered sensitivity or motor function, because some patients have relief when eliminating these from their diet. Altered intestinal permeability enabling passage of food antigens into the mucosa leading to prolonged stimulation of the intestinal mucosal immune system and the ENS is also a possible cause for functional abdominal pain.

EVALUATION AND DIAGNOSIS
While evaluating a patient with chronic abdominal pain, distinguishing organic pain and functional pain can be challenging. A wide range of potential organic causes of chronic abdominal pain (see Table 306-13) must be considered before establishing a diagnosis of functional pain (nonorganic). Frequently cited causes of chronic abdominal pain include constipation, esophagitis, gastritis, inflammatory bowel disease, and possibly giardiasis. There is little evidence that the frequency, severity, or location of the pain helps to distinguish between organic and nonorganic pain. It is controversial whether nighttime awakening because of pain is concerning for organic disorders or if it can also be seen with functional pain syndromes.

Children with chronic abdominal pain might have associated headaches, anorexia, nausea, vomiting, excessive gas, diarrhea or constipation, and joint pain, but this does not help distinguish between functional and organic disorder. Negative lifestyle events and high life stress levels also do not help to distinguish organic and nonorganic pain, despite several reports of higher levels of life stress in children with chronic abdominal pain. Daily stressors may increase the likelihood for pain episodes, but there is no evidence that psychologic issues distinguishes between organic and nonorganic abdominal pain. Nonetheless, it is important to investigate and manage the psychologic factors because there is evidence suggesting that children with chronic abdominal pain have more anxiety and depression symptoms. Whether this causes pain or is the result of pain is not known.

Children with functional pain do not have higher levels of conduct disorder or oppositional behavior compared to the controls but they can be more prone to emotional symptoms or psychiatric disorders later in life. Parents of patients with functional abdominal pain have more symptoms of somatization, anxiety, and depression. Both the family and the affected child (when the child gets to adult age) have a higher incidence of irritable bowel syndrome (IBS).

A thorough history and physical examination will identify the alarm symptoms and signs (Tables 342-4 and 342-5). The presence of alarm symptoms and signs warrants further investigation. The absence of alarm symptoms and signs, a normal physical examination, and a normal stool Hemoccult test is sufficient for an initial diagnosis of functional abdominal pain. The laboratory, radiologic, or endoscopic approach to children with chronic abdominal pain should be individualized, depending on the findings suggested by a detailed history and physical examination.

Laboratory studies may be unnecessary if the history and physical examination lead to a diagnosis of functional abdominal pain. Nonetheless, medical tests can reassure the patient and family, and at times the physician, if there is significant functional disability and poor quality of life. A complete blood cell count, sedimentation rate, C-reactive protein, basic chemistry panel, celiac panel, stool culture, stool test for ova and parasites, and urinalysis are reasonable screening studies. The risk of celiac disease may be 4 times higher in these patients compared with the general population. Elevated stool calprotectin levels usually suggest an inflammatory etiology.

If indicated, an ultrasound examination of the abdomen can give information about kidneys, gallbladder, and pancreas; with lower
abdominal pain, a pelvic ultrasonogram may be indicated. An upper GI x-ray series is indicated if one suspects a disorder of the stomach or small intestine.

H. pylori infection does not seem to be associated with chronic abdominal pain, but in patients with symptoms suggesting gastritis or ulcer, an H. pylori test (fecal H. pylori antigen) may be performed. Breath hydrogen testing is done for ruling out lactose or sucrose malabsorption. Lactose intolerance is so common that the finding may be coincidental, and the clinician must be cautious in attributing chronic abdominal pain to this condition.

Esophagogastroduodenoscopy is indicated with symptoms that suggest persistent upper GI pathology. In the absence of this suspicion, esophagogastroduodenoscopy is unlikely to identify an abnormality and is usually not necessary.

**TREATMENT**

Making a positive diagnosis of functional abdominal pain is important and can be done by the primary care pediatrician in most 4-18 yr old children with chronic abdominal pain if there are no alarm symptoms or signs, a normal physical examination, and a negative stool occult blood test. In practice, on many occasions children do not get a conclusive diagnosis of functional abdominal pain. This can lead to unwarranted referrals and increased anxiety to the patient and family. Even if a diagnostic evaluation is initiated during the initial office visit, a discussion about functional abdominal pain as the most likely diagnosis during that visit will help the patient and family to understand the diagnosis better. Close following and counseling by one consistent healthcare provider is essential.

The most important component of the treatment is reassurance and education of the child and family. The child and family need to be reassured that no evidence of a serious underlying disorder is present. The family and the child with functional pain might worry about the inability to identify an organic cause and may be resistant to a diagnosis of nonorganic disease. Explanation in simple language that although the pain is real, there is no underlying serious disorder usually alleviates the anxiety in the patient and family. Children of families that do not accept a functional cause of the symptoms are more likely to have persistent somatic complaints and school absences. The parents should be instructed to avoid reinforcing the symptoms with secondary gain. If children have missed school or have been removed from routine activities because of the pain, it is important that they return to regular activities.

Treatment goals should be set for return to function and minimizing pain. Complete disappearance of pain would be an unreasonable goal to set. Cognitive-behavioral therapy is helpful in the short term for managing pain and functional disability (Table 342-6). Biofeedback, guided imagery, and relaxation techniques have been useful in some children with functional pain. Even though studies do not show consistent benefits from medications, time-limited use of medications is usually part of the multidisciplinary approach. The commonly used medications include acid suppressants for dyspepsia symptoms, antispasmodics, and low-dose amitriptyline. For chronic abdominal pain with IBS symptoms, antidiarrheals and nonstimulating laxatives are used. Peppermint oil for 2 wk improves IBS symptoms in children. There is no evidence that a lactose-restricted diet or fiber supplements decrease the frequency of attacks in chronic abdominal pain in children. Proton pump inhibitors or visceral muscle relaxants (anticholinergics) are used empirically but are often unhelpful in the absence of specific indication.

**Irritable Bowel Syndrome**

IBS is characterized as a chronic FGID associated with abdominal pain or discomfort and altered bowel function without evidence of an inflammatory, anatomic, metabolic, or neoplastic process. Table 342-7 presents the Rome III diagnostic criteria for diagnosing IBS in children and adolescents.

Abdominal pain is episodic, cramping, or aching, usually in the lower abdomen, and often relieved by defecation. There may be abdominal discomfort, bloating, and flatulence. Diarrhea and constipation alone or in an alternating pattern must be present. The diarrhea is often watery and frequent and is associated with pain, the passage of mucus per rectum, and a feeling of incomplete emptying. The constipation is associated with a decreased stooling frequency and the passage of hard stools. Symptoms may be traced back to childhood or following an episode of presumed bacterial or viral gastroenteritis. It is important to rule out organic causes of abdominal pain and altered bowel patterns, especially celiac disease, even in the absence of the classic features of this disease.

Many dietary modifications have been suggested for relief of symptoms but not proven. Restriction of dietary fermentable oligosaccharides, disaccharides, monosaccharides, and polyols in some studies have shown symptom relief.

The effectiveness of analgesics, antispasmodics, sedatives, and antidepressants is currently unknown.

Probiotics are reported to be helpful in diarrhea predominant IBS, but larger trials are necessary to prove probiotics are beneficial. Management focuses on the dominant symptoms. Pain has been managed with cognitive-behavioral therapy, pain clinic referrals, peppermint, antispasmodic agents, and tricyclic antidepressant agents (amitriptyline). Diarrhea has been managed with loperamide, oral nonabsorbable antibiotics, and 5-HT₃ antagonists (alosetron). Constipation is managed with fiber (psyllium), increased fluid intake, lactulose, 5-HT₄ agonists (tegaserod), and selective C2 chloride channel–activating agents. In all medication trials, there is often a high response to placebo.

Chapter 343

Acute Appendicitis

John J. Aiken and Keith T. Oldham

Acute appendicitis remains the most common acute surgical condition in children and a major cause of childhood morbidity. While prompt appendectomy remains the mainstay of treatment, management has changed substantially in the past several decades with improved antibiotic regimens, advances in imaging techniques, percutaneous drainage procedures by interventional radiologists, initial nonoperative management in select cases, and the use of laparoscopy. Approximately 100,000 children are treated in children's hospitals for appendicitis each year. The incidence of appendicitis increases with age, from a rate of 1-2 per 10,000 children from birth to 4 yr of age, to a rate of 19-28 per 10,000 children younger than 14 yr annually. Children have a lifetime risk of ≈7% and appendicitis is diagnosed in 1-8% of children presenting to the emergency department for evaluation of abdominal pain. The misdiagnosis of appendicitis is second only to meningitis as a cause of medical malpractice suits in pediatric emergency care. Mortality is low (<1%), but morbidity remains high, mostly in association with complicated (perforated) appendicitis. Advances in surgical (laparoscopy) and imaging technology have significantly escalated treatment-related costs without demonstrable improvement in patient outcomes. In addition, there are marked variations in practice patterns and resource utilization in the evaluation and management of appendicitis. Children have a higher perforation rate than adults and up to 40% of children present with complicated disease.

PATHOLOGY

The clinical entity of acute appendiceal inflammation followed by perforation, abscess formation, and peritonitis is most likely a disease of multiple etiologies, the final common pathway of which involves invasion of the appendiceal wall by bacteria. One pathway to acute appendicitis begins with luminal obstruction; inspissated fecal material, lymphoid hyperplasia, ingested foreign body, parasites, and tumors have been implicated. Obstruction of the appendiceal lumen initiates a progressive cascade including increasing intraluminal pressures from bacterial proliferation and continued secretion of mucus, elevated intraluminal pressure, lymphatic and venous congestion and edema, impaired arterial perfusion, ischemia of the wall of the appendix, bacterial invasion of the appendiceal wall, and necrosis. This progression correlates with the clinical disease progression from simple appendicitis to gangrenous appendicitis and, thereafter, appendiceal perforation. Submucosal lymphoid follicles, which can obstruct the appendiceal lumen, are few at birth but multiply steadily during childhood, reaching a peak in number during the teen years, when acute appendicitis is most common, and declining after age 30 yr. Because of this prominence of lymphoid tissue, some have hypothesized that the appendix may have an immune function similar to that of the thymus or bursa of Fabricius. Fecaliths and appendicitis are more common in developed countries with refined, low-fiber diets than in developing countries with a high-fiber diet; no causal relationship has been established between lack of dietary fiber and appendicitis.

The finding that <50% of specimens from cases of acute appendicitis demonstrate luminal obstruction on radiographic, gross, or pathologic examination has prompted investigations of alternative etiologies. Enteric infection likely plays a role in many cases in association with mucosal ulceration and invasion of the appendiceal wall by bacteria. Bacteria such as Versinia, Salmonella, and Shigella spp., and viruses such as infectious mononucleosis, mumps, coxsackievirus B, and adenovirus, are implicated. In addition, case reports demonstrate the occurrence of appendicitis from ingested foreign bodies, in association with carcinoid tumors of the appendix or Ascaris and following blunt abdominal trauma. Children with cystic fibrosis have an increased incidence of appendicitis; the cause is believed to be the abnormal thickened mucus. Appendicitis in neonates is rare and warrants diagnostic evaluation for cystic fibrosis and Hirschsprung disease.

A primary focus in the management of acute appendicitis is avoidance of sepsis and the infectious complications leading to increased morbidity; mostly seen in association with perforation. Bacteria can be cultured from the serosal surface of the appendix before microscopic or gross perforation and bacterial invasion of the mesenteric veins can result in portal vein or superior mesenteric vein sepsis (pyelophlebitis), thrombosis, and liver abscess. Subsequent to perforation, the microbiologic fecal contamination may be localized to the right lower quadrant (RLQ) or pelvis by the omentum and adjacent loops of bowel, resulting in a localized abscess or inflammatory mass (phlegmon), or, alternatively, the fecal contamination may spread through the peritoneal cavity, causing diffuse peritonitis. Young children typically have a poorly developed omentum and are often unable to control the local infection. Perforation and abscess formation with appendicitis can lead to fistula formation in adjacent organs, scrotal cellulitis and abscess through a patent processus vaginalis (congenital indirect inguinal hernia), or small bowel obstruction.

CLINICAL FEATURES

Appendicitis is most common in older children, with peak incidence between the ages of 12 and 18 yr; it is rare in children younger than 5 yr of age (<5% of cases) and extremely rare (<1% of cases) in children younger than 3 yr of age. It affects boys slightly more often than girls and whites more often than blacks in the United States. There is a seasonal peak incidence in autumn and spring. There appears to be a familial predisposition in some cases, particularly in children in whom appendicitis develops before age 6 yr. Perforation in appendicitis is more common in children compared to adults, particularly in young children; with perforation rates as high as 82% for children younger than 5 yr and approaching 100% in infants. There is an increased incidence of perforated appendicitis in children of minority race and children with Medicaid health insurance.

Appendicitis in children has an immensely broad spectrum of clinical presentation. The signs and symptoms can be classic or often atypical and quite variable depending on the timing of presentation, the patient's age, the location of the appendix, and individual variability in the evolution of the disease process. Children early in the disease process can appear well and demonstrate minimal symptoms, subtle findings on physical examination, and normal laboratory studies; those with perforation and advanced peritonitis often demonstrate severe illness with bowel obstruction, renal failure, and septic shock. While the classic presentation of acute appendicitis is well described, this represents <50% of cases; therefore, the majority of cases of appendicitis have an “atypical” presentation. The illness typically begins insidiously with a brief (several hours) period of generalized malaise and anorexia; the child does not appear ill and the family is not likely to seek consultation assuming the child has “stomach flu” or a viral syndrome. Unfortunately, if the diagnosis is appendicitis, the illness escalates rapidly with progressive abdominal pain followed by vomiting, and appendiceal perforation is likely to occur within 48 hr of the
onset of illness. The opportunity for diagnosis before perforation in acute appendicitis in children is generally brief (~36-48 hr).

Abdominal pain is consistently the primary and often the first symptom; beginning shortly (hours) after the onset of illness. As with other visceral organs, there are no somatic pain fibers within the appendix; therefore, early appendiceal inflammation results in pain which is vague, poorly localized, unrelated to activity or position, often colicky, and periumbilical in location as a result of visceral inflammation from a distended appendix. Progression of the inflammatory process in the next 12-24 hr leads to involvement of the adjacent parietal peritoneal surfaces, resulting in somatic pain localized to the RLQ.

It is important to note the position of the appendix can vary greatly. In 50% of the population it is located in a retrocecal position; likely resulting in a delayed presentation. In others it is located over the pelvic brim, occasionally descending low down in the pelvis. The position of the appendix is a critical factor affecting interpretation of presenting signs and symptoms and accurate diagnosis. The pain becomes steady and more severe and is exacerbated by movement. The child often describes marked discomfort with the “bumpy” car ride to the hospital, moves cautiously, and has difficulty getting onto the examining room stretcher. Nausea and vomiting occur in more than half the patients, and usually follow the onset of abdominal pain by several hours. Anorexia is a classic and consistent finding in acute appendicitis, but occasionally, affected patients are hungry. Diarrhea and urinary symptoms are also common, particularly in cases of perforated appendicitis when there is likely inflammation near the rectum and possible abscess in the pelvis. As it progresses, appendicitis is often associated with adynamic ileus; leading to the complaint of constipation and possible misdiagnosis. Because enteric infections can cause appendicitis, diarrhea may be the initial manifestation and gastroenteritis may be the assumed diagnosis. In contrast to gastroenteritis, the abdominal pain in appendicitis is constant (not cramping or relieved by defecation), the emesis may become bile stained and persistent, and the clinical course worsens steadily rather than demonstrating a waxing and waning pattern. Fever is common and typically low-grade unless perforation has occurred. Most patients demonstrate at least mild tachycardia.

The temporal progression of symptoms from vague, mild pain, malaise, and anorexia to severe localized pain, fever, and vomiting typically occurs rapidly, in 24-48 hr in the majority of cases. If the diagnosis is delayed beyond 36-48 hr, the perforation rate exceeds 65%. A period after perforation of lessened abdominal pain and acute symptoms has been described, presumably with the elimination of pressure within the appendix. If the omentum or adjacent intestine is able to wall off the infectious process, the evolution of illness is less predictable and delay in presentation is likely. If perforation leads to diffuse peritonitis, the child generally has escalating diffuse abdominal pain and rapid development of toxicity evidenced by dehydration and signs of sepsis including hypotension, oliguria, acidosis, and high-grade fever. When several days have elapsed in the progression of appendicitis, patients often develop signs and symptoms of developing small bowel obstruction. If the appendix is retrocecal, appendicitis predictably evolves more slowly and patients are likely to relate 4-5 days of illness preceding evaluation. The pain is typically more lateral and posterior and can mimic the symptoms associated with septic arthritis of the hip or a psoas muscle abscess. Occasionally patients will complain of urinary symptoms, presumably related to inflammation adjacent to the ureter and/or bladder. Painful voiding may not be from dysuria but pressure transmitted to an inflamed peritoneum.

**PHYSICAL EXAMINATION**

Although the hallmark of diagnosing acute appendicitis remains a careful and thorough history and physical examination, all clinicians know the arcane nature of acute appendicitis, the consistent or typical clinical features are not present in all patients, and the diagnosis can be a humbling experience even for the most experienced clinicians. A primary focus of the initial assessment is attention to the temporal evolution of the illness in relation to specific presenting signs and symptoms. In many children, appendicitis can be confidently diagnosed based on history and physical examination alone, and the children can thus be spared the treatment delay, expense, and possible radiation exposure associated with imaging studies.

Physical examination begins with inspection of the child’s demeanor as well as the appearance of the abdomen. Because appendicitis most often has an insidious onset, children rarely present <12 hr from the onset of illness, and the children who do present early are likely to have minimal findings. Children with early appendicitis (18-36 hr) typically appear mildly ill and move tentatively, hurriedly forward and, often, with a slight limp favoring the right side. Supine, they often lie quietly on their right side with their knees pulled up to relax the abdominal muscles, and when asked to lie flat or sit up, they move cautiously and might use a hand to protect the RLQ.

Early in appendicitis, the abdomen is typically flat; abdominal distention suggests more advanced disease characteristic of perforation or developing small bowel obstruction. Auscultation can reveal normal or hyperactive bowel sounds in early appendicitis, which are replaced by hypactive bowel sounds as the disease progresses to perforation. The judicious use of morphine analgesia to relieve abdominal pain does not change diagnostic accuracy or interfere with surgical decision making, and patients should receive adequate pain control.

Localized abdominal tenderness is the single most reliable finding in the diagnosis of acute appendicitis. McBurney described the classic point of localized tenderness in acute appendicitis, which is the junction of the lateral and middle thirds of the line joining the right anterior–superior iliac spine and the umbilicus, but the tenderness can also localize to any of the aberrant locations of the appendix. Localized tenderness is a later and less-consistent finding when the appendix is retrocecal in position (>50% of cases). In cases of an appendix localized entirely in the pelvis, the tenderness on abdominal examination may be minimal and best appreciated on rectal examination.

A gentle touch on the child’s arm at the beginning of the examination with the reassurance that the abdominal examination will be similarly gentle can help to establish trust and increase the chance for a reliable and reproducible examination. The examination is best initiated in the left lower abdomen, so that the immediate part of the exam is not uncomfortable, and conducted in a counterclockwise direction moving gently to the left upper abdomen, right upper abdomen, and, lastly, the right lower abdomen. This should alleviate anxiety, allow relaxation of the abdominal musculature, and enhance trust. The examiner makes several “circles” of the abdomen with sequentially less pressure. A soft, compressible, non-tender abdominal wall is reassuring. In appendicitis, any abdominal wall movement, including coughing (Dunphy sign), may elicit pain. A consistent finding in acute appendicitis is guarding of the overlying rectus muscle. This rigidity may be voluntary, to protect the area of tenderness from the examiner’s hand, or involuntary, secondary to peritonitis causing spasm of the overlying muscle.

Examination findings must be interpreted relative to the temporal evolution of the illness. Abdominal tenderness may be vague or even absent early in the course of appendicitis and is often diffuse after rupture. Rebound tenderness and referred tenderness (Rovsing sign) are also consistent findings in acute appendicitis but not always present. Rebound tenderness is elicited by deep palpation of the abdomen followed by the sudden release of the examining hand. This is often very painful to the child and has demonstrated poor correlation with peritonitis, so it should be avoided. Gentle finger percussion is a better test for peritoneal irritation. Similarly, digital rectal examination is uncomfortable and unlikely to contribute to the evaluation of appendicitis in most cases of appendicitis in children. Psoas and obturator internus signs are pain with passive stretch of these muscles. The psoas sign is elicited with active right thigh flexion or passive extension of the hip and typically positive in cases of a retrocecal appendix. The obturator sign is demonstrated by adductor pain after internal rotation of the flexed thigh and typically positive in cases of a pelvic appendix. Physical examination may demonstrate a mass in the RLQ representing an
inflammatory phlegmon around the appendix or a localized abscess (fluid collection).

**DIAGNOSTIC STUDIES**

**Laboratory Findings**

A variety of laboratory tests have been used in the evaluation of children with suspected appendicitis. Individually, none are very sensitive or specific for appendicitis, but collectively they can affect the clinician’s level of suspicion and decision-making to proceed with pediatric surgery consultation, discharge, or imaging studies. Findings should be interpreted with attention to the temporal evolution of the illness.

A complete blood count with differential and urinalysis are commonly obtained. The leukocyte count in early appendicitis may be normal and typically is only mildly elevated with a left shift (11,000-16,000/mm³) as the illness progresses in the initial 24-48 hr. Whereas a normal white blood cell (WBC) count never completely eliminates appendicitis, a count <8,000/mm³ in a patient with a history of illness longer than 48 hr should be viewed as highly suspicious for an alternative diagnosis. The leukocyte count may be markedly elevated (>20,000/mm³) in perforated appendicitis and rarely in nonperforated cases; a markedly elevated WBC count, other than in cases of advanced, perforated appendicitis, should raise suspicion of an alternative diagnosis.

Urinalysis often demonstrates a few white or red blood cells, as a result of the proximity of the inflamed appendix to the ureter or bladder, but it should be free of bacteria. The urine is often concentrated and contains ketones from diminished oral intake and vomiting. Gross hematuria is uncommon and suggests primary renal pathology such as Henoch-Schönlein purpura.

Electrolytes and liver chemistries are generally normal unless there has been a delay in diagnosis, leading to severe dehydration and/or sepsis. Amylase and liver enzymes are only helpful to exclude alternative diagnoses such as pancreatitis and cholecystitis and are not obtained if appendicitis is the strongly suspected diagnosis. Electrolytes are most helpful to assess level of illness and direct fluid resuscitation, but rarely aid accurate diagnosis.

C-reactive protein increases in proportion to the degree of appendiceal inflammation but is nonspecific and not widely used. Serum amyloid A protein is consistently elevated in patients with acute appendicitis with a sensitivity and specificity of 86% and 83%, respectively.

The Pediatric Appendicitis Score combines history, physical, and laboratory data to assist in the diagnosis (Table 343-1). Scores of 3 and 7 are ≥5 and 7 are ≥8 are highly associated with appendicitis. Scores between 3 and 7 warrant further evaluation or diagnostic studies. Nonetheless, no scoring system is perfectly sensitive or specific and none have demonstrated reliability above history and physical examination by an experienced clinician.

**Radiologic Studies**

Following a thorough initial evaluation; history, physical examination, and review of vital signs and laboratory studies, if the diagnosis is uncertain, advanced radiographic studies can improve diagnostic accuracy.

**Plain Radiographs**

Plain abdominal radiographs may be helpful in select cases of abdominal pain/suspected appendicitis. Plain abdominal x-rays can demonstrate several findings in acute appendicitis including sentinel loops of bowel and localized ileus, scoliosis from psoas muscle spasm, a colonic air-fluid level above the right iliac fossa (colon “cutoff” sign), a RLQ soft-tissue mass, or a calcified appendicolith (5-10% of cases), but they are normal in 50% of patients, have a low sensitivity, and are not generally recommended (Fig. 343-1). Plain films are most helpful in evaluating complicated cases in which small bowel obstruction or free air is suspected.

**Ultrasound**

Ultrasound is usually utilized for diagnostic accuracy in the evaluation of acute appendicitis and has demonstrated >90% sensitivity and specificity in pediatric centers experienced with the technique. Graded abdominal compression is used to displace the cecum and ascending colon and identify the appendix, which has a typical target appearance (Fig. 343-2). The ultrasound criteria for appendicitis include wall thickness ≥6 mm, luminal distention, lack of compressibility, a complex mass in the RLQ, or an appendicolith. The visualized appendix usually

**Figure 343-1** Calcified appendicoliths are seen in a coned-down anteroposterior view of the right lower quadrant (A) and in the resected appendix of a 10-yr-old girl with acute appendicitis (B). (From Kuhn JP, Slovis TL, Haller JO: Caffrey’s pediatric diagnostic imaging, vol 2, ed 10, Philadelphia, 2004, Mosby, p. 1682.)
The main limitation of ultrasound is an inability to visualize the appendix, which is reported in up to 20% of cases. A normal appendix must be visualized to exclude appendicitis by ultrasound. Certain conditions predictably decrease the sensitivity and reliability of ultrasound for appendicitis, including obesity, bowel distention, and pain, which interfere with the exam. Major advantages of ultrasound include its easy availability, rapid method, low cost, and freedom from need for patient preparation and ionizing radiation. Ultrasound can be particularly helpful in adolescent girls, a group with a high negative appendectomy rate (normal appendix found at surgery), because of its ability to evaluate for ovarian pathology without ionizing radiation. A diagnostic or normal ultrasound exam eliminates the need for CT and should be considered the first exam in a center experienced with the technique.

CT Scan

CT scan had been the gold standard imaging study for evaluating children with suspected appendicitis, but carries the significant negative effects of radiation exposure and increased costs. It should be used only in carefully selected patients and always observing the reduced radiation dosage recommendations for children. CT examination can be performed in many ways, including standard CT scan, helical CT scan, with or without oral and intravenous contrast, examination of both the abdomen and pelvis or pelvis alone, focused appendiceal CT scan, and focused appendiceal CT scan with rectal contrast. All of these techniques have demonstrated >95% sensitivity and specificity for acute appendicitis. Findings on CT scan consistent with appendicitis include a distended (dilated >7 mm) thick-walled appendix, inflammatory streaking of surrounding mesenteric fat, and a pericecal phlegmon or abscess (Figs. 343-3 and 343-4). In addition, appendicoliths are more readily demonstrated on CT scan (40-50%) than on plain radiographs (5-15%). CT scan may be most useful in advanced appendicitis to identify and guide percutaneous drainage of fluid collections and identification of an inflammatory mass, which might prompt a plan for initial nonoperative management. The use of CT scan to “rule out” acute appendicitis and avoid the need (and expenditures) of in-hospital admission is suspect as in early appendicitis CT findings are predictably subtle and in more advanced cases CT scan should be unnecessary as an accurate diagnosis should be able to be made on careful history and physical examination.

Disadvantages of CT scan include; greater cost; radiation exposure; possible need for intravenous, oral, or rectal contrast; and possible need for sedation. Children have an increased sensitivity to radiation and a longer life ahead to potentially develop a radiation-induced malignancy. A single CT scan has been reported to confirm a 1 in 1,000 lifetime mortality risk, and the risk has been reported as high as 1 in 550 in children younger than age 5 yr. Oral contrast is problematic if
Differential diagnosis, even limited to common conditions, includes gastroenteritis, mesenteric adenitis, Meckel diverticulitis, inflammatory bowel disease, diabetes mellitus, sickle cell disease, streptococcal pharyngitis, lower lobe pneumonia, cholecystitis, pancreatitis, urinary tract infection, infectious enteritis, and, in girls, ovarian torsion, ectopic pregnancy, ruptured ovarian cysts, and pelvic inflammatory disease (including tuboovarian abscess). Intestinal tract lymphoma, tumors of the appendix (carcinoid in children), and ovarian tumors are rare but can also masquerade as acute appendicitis. In patients with pylonephritis, the fever and WBC count are likely much higher, symptoms of dysuria will be present, and the tenderness is located more in the flank or costovertebral angle. Rarely, appendicitis may recur in the stump of a previous appendectomy. Children younger than 3 yr of age and adolescent girls have historically proven to be at particularly high risk for an incorrect diagnosis.

Most important is differentiation of the patients with gastroenteritis, which is the most common misdiagnosis in the child with appendicitis. The time course of illness (hours, days, weeks) leading to presentation is a critical component of the history. The classic patient with acute appendicitis describes abdominal pain as the preeminent symptom. In general, symptoms of systemic illness such as headache, chills, and myalgias indicate that a patient does not have appendicitis. Acute appendicitis most often begins insidiously as generalized malaise or anorexia, but there is early (within hours) onset of abdominal pain and the illness typically escalates rapidly in the initial 24-48 hr. Most patients with acute appendicitis have 1-3 episodes of vomiting in the initial 24-48 hr of illness; multiple episodes of vomiting are unusual in early appendicitis. In contrast, when gastroenteritis is the diagnosis, diarrhea and vomiting are more likely to be predominant symptoms early in the illness, and abdominal pains may seem associated with the frequent episodes of diarrhea and vomiting. In patients with an acute presentation (<72 hr of illness), vomiting preceding pain, large-volume diarrhea, large amounts of nonbilious vomiting, and high fever suggest gastroenteritis. In addition, patients with appendicitis typically have normal or hypovolemic bowel sounds, whereas gastroenteritis typically produces persistently hyperactive bowel sounds. From the onset of illness, the child with appendicitis typically has a steadily deteriorating clinical course, whereas the child with gastroenteritis may have an undulating course, at times feeling better and other times feeling worse.

In the classic child with acute appendicitis who presents within 48 hr of the onset of illness, the WBC count can be low, normal, or elevated but is only rarely elevated >20,000/mm³. WBC counts in this range should prompt consideration of alternative diagnoses.

A child who presents with a history of illness of longer than 3-4 days is often more challenging. If the diagnosis is appendicitis, perforation has likely occurred and the child's presentation should evidence signs and symptoms of localized abscess/phlegmon in the RLQ or diffuse peritonitis. At this point in the illness, the WBC count should be elevated (>12,000/mm³) with a left shift; a WBC count <7,000/mm³ with a lymphocytosis is distinctly unusual in advanced appendicitis and more typical of gastroenteritis. A slightly slower progression of illness is also typical when the appendix is in a retrocecal position and symptoms and anterior abdominal wall tenderness typically are slower to evolve.

An abnormal hemogram combined with purpuric skin lesions, arthritis, and nephritis suggests a diagnosis of Henoch-Schönlein purpura or hemolytic-uremic syndrome. Torsion of an undescended testis and epididymitis are common but should be discovered on physical examination. Meckel diverticulitis is an infrequent condition, but the clinical presentation closely mimics appendicitis and the diagnosis is usually made at surgery. Primary spontaneous peritonitis is classically seen in prepubertal girls is often mistaken for appendicitis.

It should be recognized that "missed" appendicitis is the most common cause of small bowel obstruction in children without history of prior abdominal surgery. Atypical presentations of appendicitis are expected in association with other conditions such as pregnancy, Crohn disease, steroid treatment, and immunosuppressive therapy.

**Figure 343-4** A, Precontrast-enhanced CT reveals an appendicolith (arrow) in perforated appendicitis. B, Postcontrast-enhanced CT (1 cm below the level in A) reveals intraluminal air in the appendix (curved arrow) associated with ileal wall enhancement in perforated appendicitis. (From Yeung KW, Chang MS, Hsiao CP: Evaluation of perforated and nonperforated appendicitis with CT, Clin Imaging 28(6):422–427, 2004.)

Appendicitis is confirmed, because of the risk for aspiration at induction of anesthesia. Because the finding of fat stranding in surrounding tissues is a key component of CT evaluation for appendicitis, CT is less reliable in thin children with minimal body fat. For this reason, rectal contrast can increase diagnostic accuracy in this group. CT imaging is also helpful in demonstrating nonappendiceal causes of abdominal pain.

Following initial evaluation, if the diagnosis of acute appendicitis is suspected but uncertain, it is advisable to obtain pediatric surgical consultation before proceeding with a CT scan. An alternative approach to diminish the use of CT scans is the emerging use of observational units for a period up to 23 hr to follow clinical disease progression. Acute appendicitis is most often a rapidly progressive illness and signs and symptoms including fever, tachycardia, nausea and/or vomiting, and focal tenderness, which become more prominent despite intravenous fluids will often lower negative appendectomy rates and enable an accurate diagnosis without the need for advanced imaging.

**MRI/White Blood Cell Scan**

MRI is at least equivalent to CT in diagnostic accuracy for appendicitis and does not involve ionizing radiation. The use of MRI in the evaluation of appendicitis is limited because it is less available, more costly, often requires sedation, and does not offer equivalent access for drainage of fluid collections. MRI may prove most useful in adolescent girls when advanced imaging is needed. Radionuclide-labeled WBC scans have also been used in some centers in evaluating atypical cases of possible appendicitis in children and demonstrated a high sensitivity (97%) but only modest specificity (80%).

**DIFFERENTIAL DIAGNOSIS**

The list of illnesses that can mimic acute appendicitis is extensive because many gastrointestinal, gynecologic, and inflammatory disorders can manifest with similar illness history, signs, and symptoms. Acute appendicitis most often begins insidiously as generalized malaise or anorexia, but there is early (within hours) onset of abdominal pain and the illness typically escalates rapidly in the initial 24-48 hr of illness; multiple episodes of vomiting are unusual in early appendicitis. In contrast, when gastroenteritis is the diagnosis, diarrhea and vomiting are more likely to be predominant symptoms early in the illness, and abdominal pains may seem associated with the frequent episodes of diarrhea and vomiting. In patients with an acute presentation (<72 hr of illness), vomiting preceding pain, large-volume diarrhea, large amounts of nonbilious vomiting, and high fever suggest gastroenteritis. In addition, patients with appendicitis typically have normal or hypovolemic bowel sounds, whereas gastroenteritis typically produces persistently hyperactive bowel sounds. From the onset of illness, the child with appendicitis typically has a steadily deteriorating clinical course, whereas the child with gastroenteritis may have an undulating course, at times feeling better and other times feeling worse.

In the classic child with acute appendicitis who presents within 48 hr of the onset of illness, the WBC count can be low, normal, or elevated but is only rarely elevated >20,000/mm³. WBC counts in this range should prompt consideration of alternative diagnoses.

A child who presents with a history of illness of longer than 3-4 days is often more challenging. If the diagnosis is appendicitis, perforation has likely occurred and the child's presentation should evidence signs and symptoms of localized abscess/phlegmon in the RLQ or diffuse peritonitis. At this point in the illness, the WBC count should be elevated (>12,000/mm³) with a left shift; a WBC count <7,000/mm³ with a lymphocytosis is distinctly unusual in advanced appendicitis and more typical of gastroenteritis. A slightly slower progression of illness is also typical when the appendix is in a retrocecal position and symptoms and anterior abdominal wall tenderness typically are slower to evolve.

An abnormal hemogram combined with purpuric skin lesions, arthritis, and nephritis suggests a diagnosis of Henoch-Schönlein purpura or hemolytic-uremic syndrome. Torsion of an undescended testis and epididymitis are common but should be discovered on physical examination. Meckel diverticulitis is an infrequent condition, but the clinical presentation closely mimics appendicitis and the diagnosis is usually made at surgery. Primary spontaneous peritonitis is classically seen in prepubertal girls is often mistaken for appendicitis.

It should be recognized that "missed" appendicitis is the most common cause of small bowel obstruction in children without history of prior abdominal surgery. Atypical presentations of appendicitis are expected in association with other conditions such as pregnancy, Crohn disease, steroid treatment, and immunosuppressive therapy.
Appendicitis in association with Crohn disease often has a protracted presentation with an atypical pattern of recurring but localized abdominal pain.

The diagnosis of appendicitis in adolescent girls is especially challenging, and some series report negative appendectomy rates as high as 30–40%. Ovarian cysts are often acutely painful as a result of rupture, rapid enlargement, or hemorrhage. Rupture of an ovarian follicle associated with ovulation often causes mid-cycle lateralizing pain (mittel- schmerze), but there is no progression of symptoms and systemic illness is absent. Ovarian tumors and torsion can also mimic acute appendicitis, although ovarian torsion is typically characterized by the acute onset of severe pain and is associated with more dramatic nausea and vomiting than is normally seen in early appendicitis. In pelvic inflammatory disease, the pain is typically suprapubic, bilateral, and of longer duration. The need for accurate urgent diagnosis in girls is influenced by concern that perforated appendicitis can predispose the patient to future ectopic pregnancy or tubal infertility, although data have not consistently demonstrated increased incidence of infertility after perforated appendicitis. For these reasons, adjunct diagnostic studies (ultrasound, CT, or diagnostic laparoscopy) should be used more liberally in this group of patients to keep negative appendectomy rates low.

**DIAGNOSTIC APPROACH**

A diagnosis of acute appendicitis is made in only 50-70% of children at the time of initial assessment; negative appendectomy rates remain high (10-20%) and perforation rates (30-40%) have not changed in the past few decades.

Traditionally, early surgery in equivocal cases was the standard; aimed to minimize perforation rates and complications. Negative laparotomies for women and children communities have been common and were deemed acceptable to keep perforation rates low. Many authors have criticized these high negative laparotomy rates, citing the risks and expense of unnecessary surgery and anesthesia. In a national database, overall rupture rates for appendicitis varied from 20-76%, with a median of 36%. The median overall negative laparotomy rate (normal appendix at surgery) was 2.6%, significantly lower than traditionally reported rates of 10-20%. The lack of consensus in management approach is reflected by the fact that the use of diagnostic imaging in cases of suspected appendicitis varied from 18-89%.

Some clinicians remain steadfast to the primacy of a careful history and physical examination and rarely order advanced imaging studies. The initial assessment, along with the history and physical examination, may include a complete blood count with differential, urinalysis, and plain films (chest and abdominal series). If the initial assessment leads to a high level of suspicion for appendicitis, pediatric surgical consultation should be the next step, with the likelihood of prompt appendectomy without further studies. If the initial evaluation suggests a nonsurgical diagnosis and a low concern for appendicitis, the child may be discharged with family education regarding the natural history and progression of acute appendicitis and advice to return for repeat evaluation if the child is not improving on liquids and a bland diet in the next 24 hr. This approach has demonstrated high sensitivity and specificity (>90%) at certain institutions, but collective data from many centers have not been able to reproduce this degree of accuracy.

Previous reports recommending CT scans in all equivocal cases to minimize perforation rates and morbidity are not supported in the current climate to reduce the use of CT scan and ionizing radiation. It seems likely that if imaging studies are obtained in all patients with equivocal presentations and a brief duration of illness (<24 hr), the false-negative rate of the imaging studies will increase. Maximum benefit and effectiveness of advanced imaging is obtained when it is used selectively in children for whom the diagnosis is equivocal after careful history and physical examination by an experienced clinician and who are not too early in the temporal evolution of the illness.

In equivocal cases, some centers proceed with a plan of active observation. Many reports substantiate improved diagnostic accuracy by observation and serial examination over a period of 12-24 hr, simplifying the eventual decision to proceed with appendectomy, discharge the patient, or proceed with advanced imaging studies, and report no correlation between surgical morbidity and timing of surgery. The use of observation units, where the child may be observed with intravenous fluids, serial vital signs, and planned repeat physical examination in 6–12 hr. is a strategy gaining increased popularity. At the end of a period of observation, the clinician should decide to discharge the patient based on improved clinical status, proceed to appendectomy, or proceed to further imaging evaluation. Advanced imaging in this equivocal group will be more reliable further into the disease process and hopefully can minimize the negative laparotomy rate without increasing the perforation rate (missed or delayed diagnosis). Less than 2% of children's appendices perforate while under observation.

A thoughtful approach in equivocal cases of appendicitis is to begin with ultrasound if it is available and the hospital has experience with ultrasound for possible appendicitis. In 1 study, ultrasound decreased the need for CT scan in 22% of patients. If ultrasound imaging is inconclusive, the next diagnostic step could be pediatric surgical consultation, a brief period of observation followed by clinical reevaluation and CT scan if the diagnosis remains equivocal. The period of observation (12-24 hr) can occur at home provided the patient is physiologically well; a hospital-based observational unit has the advantage of being able to provide intravenous fluids. CT scan may be used as the first-line test in obese patients, in cases of probable advanced or perforated appendicitis, or when there is gaseous distention of the bowel. Practice guidelines have decreased both length of stay and costs without increasing complications. One such guideline employing clinical judgment and selective imaging attained a positive and negative predictive value for appendicitis of 94% and 99%, respectively.

**TREATMENT**

Once the diagnosis of appendicitis is confirmed or highly suspected, the standard treatment for acute appendicitis is most often prompt appendectomy. Some reports suggest initial nonoperative management (antibiotics and drainage of fluid collections) as an alternative option in late presentations, depending on the patient's general condition and the state of the appendix. In adults with simple appendicitis, broad-spectrum antibiotics alone have resulted in resolution of symptoms. Nonetheless, there is a 20% chance of recurrence within 1 year of conservative therapy, and of those 20% will present with perforation or a gangrenous appendix. One small nonrandomized trial of nonoperative therapy for uncomplicated appendicitis in children reported a success rate of ~90%. To be considered uncomplicated, patients had pain ≤48 hours, ultrasonographic or CT documentation of a nonruptured appendix, as well as an appendiceal diameter ≤1.1 cm without phlegmon, abscess, or fecalith. Management included a minimum of 24 hr of intravenous antibiotics (piperacillin-tazobactam or ciprofloxacin with metronidazole) followed by amoxicillin-clavulanate or ciprofloxacin with metronidazole to complete a 10-day total antibiotic course.

Emergency (middle of the night) surgery is rarely indicated, and most patients require preoperative supportive measures to stabilize vital signs and to ensure the safety of the procedure, anesthesia, and improve outcomes. In addition, often, unexpected pathology (appendiceal tumors, intestinal lymphoma, congenital renal anomalies, inflammatory bowel disease) is discovered at operation, and intraoperative consultation and frozen section may be needed. There is no correlation between timing of surgery and perforation rates or postoperative morbidity when the operation proceeds within 24-48 hr of diagnosis. In addition, appendectomy can be a challenging operation, with potential for major complications including injury to adjacent intestine, the iliac vessels, or the right ureter. The operation should proceed semielectively within 12-24 hr of diagnosis. Children with appendicitis are typically at least mildly dehydrated and require preoperative fluid resuscitation to correct hypovolemia and electrolyte abnormalities before anesthesia. Fever, if present, should be treated. Pain management begins even before a definitive diagnosis is made, and consultation of pain service, if available, is appropriate once a decision is made to proceed to surgery. In the majority of cases, preoperative management can be accomplished during the period of diagnostic evaluation and prompt appendectomy can be performed.
In patients in whom perforated appendicitis is identified at the time of diagnosis, the operation is even less urgent and proper preoperative management is more critical. When the illness is protracted owing to a delay in diagnosis or presentation, patients can demonstrate significant physiologic derangements including severe dehydration, hypotension, acidosis, and renal failure. These patients require a longer period of stabilization with fluid resuscitation and antibiotics, including, in occasional cases, admission to an intensive care unit before proceeding with more definitive management. Based on the patient’s status, findings on CT scan, and availability of experienced radiologists, the initial plan may be percutaneous drainage of fluid collections by interventional radiology and continued fluid resuscitation and antibiotics. An inflammatory mass (phlegmon) without an identifiable fluid component might initially respond to nonoperative management with fluids and antibiotics. Placement of 1 or more drainage catheters under imaging (CT or ultrasound) guidance has been successful in more than 80% of patients. Most pediatric surgeons recommend delayed appendectomy (during the same hospitalization) or interval appendectomy (4-6 wk after the initial presentation), to prevent recurrent appendicitis (>20%); this is an area of some controversy.

If diffuse peritonitis exists, most surgeons proceed promptly with appendectomy after a brief period of intravenous fluids and broad spectrum antibiotics. Others continue nonoperative management provided the patient demonstrates clinical improvement by physiologic criteria including hemodynamic stability, urine output, control of fever, and declining leukocyte count. If the patient demonstrates clinical recovery by resolution of fever, sepsis, and return of bowel function, generally a 2 wk course of oral antibiotics is completed and a decision is made regarding interval appendectomy in 6-8 wk. A child who fails to improve within 24-72 hr needs an urgent appendectomy to control sepsis. Emergency appendectomy should only be performed in the occasional circumstance when physiologic resuscitation requires urgent control of advanced peritoneal sepsis not amenable to interventional drainage or this is not available.

Antibiotics
Antibiotics substantially lower the incidence of postoperative wound infections and intraabdominal abscesses in perforated appendicitis, but their role is less well defined in simple appendicitis. The antibiotic regimen should be directed against the typical bacterial flora found in the appendix, including anaerobic organisms (Bacteroides, Clostridia, and Peptostreptococcus spp.) and Gram-negative aerobic bacteria (Escherichia coli, Pseudomonas aeruginosa, Enterobacter, and Klebsiella spp.). Gram-positive organisms are less commonly found in the colon, and the need to provide antibiotic coverage for them (primarily enterococcus) is controversial. Many antibiotic combinations have demonstrated equivalent efficacy in controlled trials in terms of wound infection rate, resolution of fever, length of stay, and incidence of complications.

For simple nonperforated appendicitis, one preoperative dose of a single broad-spectrum agent (cefoxitin) or equivalent is sufficient. The practice in perforated or gangrenous appendicitis, most surgeons prefer combination regimens such as Zosyn (piperacillin/tazobactam), ticarcillin/clavulanate, or ceftriaxone/metronidazole. The traditional “triple” antibiotic regimen (ampicillin, gentamicin, and clindamycin or metronidazole) is still effective, but adds cost and has the concern for ototoxicity. Antibiotic coverage is continued postoperatively for 3-5 days. Oral antibiotics are equally as effective as intravenous, and therefore the patient can be switched to an oral regimen and discharged once bowel function returns. This transition to oral antibiotics has significantly affected length of stay and cost in the management of perforated appendicitis.

Interval Appendectomy
Ruptured appendicitis complicated by a walled-off inflammatory mass or abscess can be treated without immediate appendectomy. This strategy is intended to avoid a predictable higher surgical complication rate and is often useful in children, in whom the overall incidence of perforation approaches 50%. In this group of patients, debate exists over the need for interval appendectomy if the child recovers well without “up front” appendectomy. The risk of developing recurrent appendicitis if the appendix is not removed is unknown, and published reports vary between 10% and 80% (most are closer to 10%). Most cases of recurrent appendicitis develop within 2 yr of the initial illness. Some authors believe interval appendectomy is unnecessary because of the low risk for recurrent appendicitis. Others support interval appendectomy to avoid recurrent appendicitis and to confirm the original diagnosis, citing an incidence of unexpected pathology in 30% of interval appendectomy specimens. The vast majority of pediatric surgeons perform interval appendectomy routinely (4-6 wk interval) after initial nonoperative management of perforated appendicitis.

Surgical Technique
Diagnostic laparoscopy and laparoscopic appendectomy (minimally invasive technique) for both simple and perforated appendicitis are the preferred approaches in most pediatric centers; the open surgery is still performed in selected cases. Laparoscopic appendectomy has significant advantages in administrative factors (cost, resource utilization, length of stay), and slight improvement in clinical outcome measures (wound infection rate, intraabdominal abscess, analgesic requirements, return to full activity), but have failed to establish an evidence-based preference between laparoscopic and open appendectomy in children. In nonperforated appendicitis, laparoscopic appendectomy appears to have lower narcotic analgesic requirements, decreased wound morbidity, and improved cosmesis, but operative times seem slightly higher and costs are almost doubled compared to the open procedure. Length of hospitalization is similar for both approaches.

The role of laparoscopy in perforated appendicitis is less well defined. There are no convincing data to recommend one approach in all patients. Most pediatric surgeons use both approaches selectively. The laparoscopic approach is used most often for obese patients, when alternative diagnoses are suspected, and in adolescent girls to better evaluate for ovarian pathology and pelvic inflammatory disease while avoiding the ionizing radiation associated with CT imaging. Injection of local anesthetic (bupivacaine) into the wound reduces postoperative pain.

Complications
Morbidity rates for appendicitis vary widely in large series from 10-45%. The principal determinant of complications is the severity of the appendicitis. In nonperforated appendicitis, an overall complication rate of 3-7% is expected. With perforation, the complication rate rises to 15-30%. The most common complications are wound infections (3-10%) and intraabdominal abscesses; both are more common after perforation. Perforation and abscess formation can also lead to fistula formation in adjacent organs. Perforation rates are consistently >80% in children younger than 5 yr of age. Delay in return to full activity and function is also predictable in perforated appendicitis. Patients with advanced appendicitis can progress to sepsis and multiorgan system failure, but generally these patients respond promptly to antibiotics, fluids, and other supportive measures preoperatively. Other potential complications include postoperative ileus, diffuse peritonitis, portal vein pylephlebitis (rare), and adhesive small bowel obstruction. Readmission rates are significantly higher in perforated appendicitis (>20%) and this has become an important marker in recent quality metrics. Mortality with appendicitis is rare (<0.5%) and seen mostly in neonates and immunocompromised patients.

INCIDENTAL APPENDICOLITHS
The question of the “incidental” appendicolith is an intriguing one for pediatric practitioners. These are patients who do not have appendicitis but are found to have an appendicolith with imaging. In adults, incidental appendicoliths identified by CT scans vary in incidence from <1% to as high as 10%. An appendicolith is defined as a calcification within the appendiceal lumen. They have a characteristic dense and laminated appearance when compared to other lower abdominal calcifications, including phleboliths (venous calcifications) and, in
girls, ovarian calcifications, most commonly seen in ovarian tumors. They can be appreciated on plain film, ultrasound, and CT scan; CT scan is the most reliable. Occasionally an appendicolith is noted during laparoscopy while visualizing a noninflamed appendix.

When an appendicolith is noted in the evaluation of a child with abdominal pain and suspected appendicitis, the finding of the appendicolith confirms the diagnosis; surgical consultation and prompt appendectomy is indicated. Appendicoliths may be noted in the evaluation of patients who have no signs of appendicitis; such as imaging obtained after trauma or for nonspecific abdominal complaints. The concern in this setting is that the appendicolith may increase the eventual development of acute appendicitis. In addition, there is the concern that appendicitis that develops in association with an appendicolith may have a rapidly escalating course and early perforation. Some physicians believe that an appendicolith may be associated with recurrent RLQ/iliac fossa pain.

Incidental appendicoliths may be transient and in most short-term follow-up studies have a low risk of subsequent acute appendicitis. The risk of subsequent appendicitis may be higher in those presenting with abdominal pain or those younger than 19 yr of age. The lifetime risk for the development of appendicitis in patients with an incidental appendicolith is approximately 5%.

Radiographically detected incidental appendicoliths are usually managed with observation, planned follow up, and patient education for signs of an acute appendicitis, while those detected during laparoscopy to rule out acute appendicitis (when the appendix is normal in appearance) may or may not undergo appendectomy. After discussing the risks and benefits with the family, and persistence of the appendicolith, some conclude that an elective appendectomy may be indicated.

Bibliography is available at Expert Consult.
In understanding the spectrum of anorectal anomalies, it is necessary to consider the importance of the sphincter complex, a mass of muscle fibers surrounding the anorectum (Fig. 344-1). This complex is the combination of the puborectalis, levator ani, external and internal sphincters, and the superficial external sphincter muscles, all meeting at the rectum. Anorectal malformations are defined by the relationship of the rectum to this complex and include varying degrees of stenosis to complete atresia. The incidence is 1 per 3,000 live births. Significant long-term concerns focus on bowel control and urinary and sexual functions.

**EMBRYOLOGY**

The hindgut forms early as the part of the primitive gut tube that extends into the tail fold in the 2nd wk of gestation. At about day 13, it develops a ventral diverticulum, the allantois or primitive bladder. The junction of allantois and hindgut become the cloaca, into which the genital, urinary, and intestinal tubes empty. This is covered by a cloacal membrane. The urorectal septum descends to divide this common channel by forming lateral ridges, which grow in and fuse by the middle of the 7th wk. Opening of the posterior portion of the membrane (the anal membrane) occurs in the 8th wk. Failures in any part of these processes can lead to the clinical spectrum of anogenital anomalies.

**Imperforate anus** can be divided into low lesions, where the rectum has descended through the sphincter complex, and high lesions, where it has not. Most patients with imperforate anus have a fistula. There is a spectrum of malformation in boys and girls. In boys, low lesions usually manifest with meconium staining somewhere on the perineum along the median raphe (Fig. 344-2A). Low lesions in girls also manifest as a spectrum from an anus that is only slightly anterior on the perineal body to a fourchette fistula that opens on the moist mucosa of the introitus distal to the hymen (Fig. 344-3A). A high imperforate anus in a boy has no apparent cutaneous opening or fistula, but it usually has a fistula to the urinary tract, either the urethra or the bladder (Fig. 344-2B). Although there is occasionally a rectovaginal fistula, in girls, high lesions are usually cloacal anomalies in which the rectum, vagina, and urethra all empty into a common channel or cloacal stem of varying length (Fig. 344-3B). The interesting category of boys with imperforate anus and no fistula occurs mainly in children with trisomy 21.

**ASSOCIATED ANOMALIES**

There are many anomalies associated with anorectal malformations (Table 344-1). The most common are anomalies of the kidneys and urinary tract in conjunction with abnormalities of the sacrum. This complex is often referred to as the **caudal regression syndrome**. Boys with a rectovesical fistula and patients with a persistent cloaca have a 90% risk of urologic defects. Other common associated anomalies are cardiac anomalies and esophageal atresia with or without tracheoesophageal fistula. These can cluster in any combination in a patient. When combined, they are often accompanied by abnormalities of the radial aspect of the upper extremity and are termed the VATERR

(vertebral, anal, tracheal, esophageal, radial, renal) or VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, limb) anomalous.

A good correlation exists between the degree of sacral development and future function. Patients with an absent sacrum usually have permanent fecal and urinary incontinence. Spinal abnormalities and different degrees of dysraphism are often associated with these defects. Tethered cord occurs in approximately 25% of patients with anorectal malformations. Untethering of the cord can lead to improved urinary and rectal continence in some patients, although it seldom reverses established neurologic defects. The diagnosis of spinal defects can be established in the first 3 mo of life by spinal ultrasound. In older patients, MRI is needed.

**MANIFESTATIONS AND DIAGNOSIS**

**Low Lesions**

Examination of a newborn includes the inspection of the perineum. The absence of an anal orifice in the correct position leads to further evaluation. Mild forms of imperforate anus are often called *anal stenosis or anterior ectopic anus*. These are probably imperforate anus with a perineal fistula. The normal position of the anus on the perineum is approximately halfway (0.5 ratio) between the coccyx and the scrotum or introitus. Although symptoms, primarily constipation, have been attributed to anterior ectopic anus (ratio: <0.34 in girls, <0.46 in boys), many patients have no symptoms.

If no anus or fistula is visible, there may be a low lesion or “covered anus.” In these cases, there are well-formed buttocks and often a thickened raphe or “bucket handle.” After 24 hr, meconium bulging may be seen, creating a blue or black appearance. In these cases, an immediate perineal procedure can often be performed, followed by a dilation program.

In a boy, the perineal (cutaneous) fistula can track anteriorly along the median raphe across the scrotum and even down the penile shaft. This is usually a thin track, with a normal rectum often just a few millimeters from the skin. Extraintestinal anomalies are seen in <10% of these patients.

In a girl, a low lesion enters the vestibule or fourchette (the moist mucosa outside the hymen but within the introitus). In this case, the rectum has descended through the sphincter complex.

Children with a low lesion can usually be treated initially with perineal manipulation and dilation. Visualizing these low fistulas is so important in the evaluation and treatment that one should avoid passing a nasogastric tube for the 1st 24 hr to allow the abdomen and bowel to distend, pushing meconium down into the distal rectum.

**High Lesions**

In a boy with a high imperforate anus, the perineum appears flat. There may be air or meconium passed via the penis (urethra) when the fistula is high, entering the bulb or prostatic urethra, or even the bladder. In *rectobulbar urethral fistulas* (the most common in boys), the sphincter mechanism is satisfactory, the sacrum may be underdeveloped, and an anal dimple is present. In *rectoprostatic urethral fistulas*, the sacrum is poorly developed, the scrotum may be bifid, and the anal dimple is near the scrotum. In *rectovesical fistulas*, the sphincter mechanism is poorly developed and the sacrum is hypoplastic or absent. In boys with trisomy 21, all the features of a high lesion may be present, but there is no fistula, the sacrum and sphincter mechanisms are usually well developed, and the prognosis is good.

In girls with high imperforate anus, there may be the appearance of a rectovaginal fistula. A true rectovaginal fistula is rare. Most are either the fourchette fistulas described earlier or are forms of a cloacal anomaly.

**Persistent Cloaca**

In persistent cloaca, the embryologic stage persists in which the rectum, urethra, and vagina communicate in a common orifice, the cloaca. It is important to realize this, because the repair often requires repositioning the urethra and vagina as well as the rectum. Children of both sexes with a high lesion require a colostomy before repair.

**Rectal Atresia**

Rectal atresia is a rare defect occurring in only 1% of anorectal anomalies. It has the same characteristics in both sexes. The unique feature of this defect is that affected patients have a normal anal canal and a normal anus. The defect is often discovered while rectal temperature is being taken. An obstruction is present approximately 2 cm above the skin level. These patients need a protective colostomy. The functional prognosis is excellent because they have a normal sphincteric mechanism (and normal sensation), which resides in the anal canal.

**APPROACH TO THE PATIENT**

Evaluation includes identifying associated anomalies (see Table 344-1). Careful inspection of the perineum is important to determine the presence or absence of a fistula. If the fistula can be seen there, it is a low lesion. The invertogram or upside-down x-ray is of little value, but a prone crosstable lateral plain x-ray at 24 hr of life (to allow time for bowel distention from swallowed air) with a radiopaque marker on the perineum can demonstrate a low lesion by showing the renal gas bubble <1 cm from the perineal skin. A plain x-ray of the entire sacrum, including both iliac wings, is important to identify sacral anomalies and the adequacy of the sacrum. An abdominal-pelvic ultrasound and voiding cystourethrogram must be performed. The clinician should also pass a nasogastric tube to identify esophageal atresia and should obtain an echocardiogram. In boys with a high lesion, the voiding cystourethrogram often identifies the rectourinary fistula. In girls with a high lesion, more invasive evaluation, including vaginoscopy and endoscopy, is often necessary for careful detailing of the cloacal anomaly.

Good clinical evaluation and a urinalysis provide enough data in 80–90% of male patients to determine the need for a colostomy. Voluntary sphincteric muscles surround the most distal part of the bowel in cases of perineal and rectourethral fistulas, and the intraluminal bowel pressure must be sufficiently high to overcome the tone of those muscles before meconium can be seen in the urine or on the perineum. The presence of meconium in the urine and a flat bottom are considered indications for the creation of a colostomy. Clinical findings consistent with the diagnosis of a perineal fistula represent an indication for an anoplasty without a protective colostomy. Ultrasound is valuable not only for the evaluation of the urinary tract, but it can also be used to investigate spinal anomalies in the newborn and to determine how close to the perineum the rectum has descended.

More than 90% of the time, the diagnosis in females can be established on perineal inspection. The presence of a single perineal orifice is a cloaca. A palpable pelvic mass (hydrocolpos) reinforces this diagnosis. A vestibular fistula is diagnosed by careful separation of the labia, exposing the vestibule. The rectal orifice is located immediately in front of the hymen within the female genitalia and in the vestibule. A perineal fistula is easy to diagnose. The rectal orifice is located somewhere between the female genitalia and the center of the sphincter and is surrounded by skin. Less than 10% of these patients fail to pass meconium through the genitalia or perineum after 24 hr of observation. Those patients can require a prone crosstable lateral film.

**OPERATIVE REPAIR**

Sometimes a perineal fistula, if it opens in good position, can be treated by simple dilation. Hegar dilators are employed, starting with a No. 5 or 6 and letting the baby go home when the mother can use a No. 8. Twice-daily dilations are done at home, increasing the size every few weeks until a No. 14 is achieved. By 1 yr of age, the stool is usually well formed and further dilation is not necessary. By the time No. 14 is reached, the examiner can usually insert a little finger. If the anal ring is soft and pliable, dilation can be reduced in frequency or discontinued.

Occasionally, there is no visible fistula, but the rectum can be seen to be filled with meconium bulging on the perineum, or a covered anus is otherwise suspected. If confirmed by plain x-ray or ultrasound of
the perineum that the rectum is <1 cm from the skin, the clinician can do a minor perineal procedure to perforate the skin and then proceed with dilation or do a simple perineal anoplasty.

When the fistula orifice is very close to the introitus or scrotum, it is often appropriate to move it back surgically. This also requires postoperative dilation to prevent stricture formation. This procedure can be done any time from the newborn period to 1 yr. It is preferable to wait until dilations have been done for several wk and the child is bigger. The anorectum is a little easier to dissect at this time. The posterior sagittal approach of Peña is used, making an incision around the fistula and then in the midline to the site of the posterior wall of the new location. The dissection is continued in the midline, using a muscle stimulator to be sure there is adequate muscle on both sides. The fistula must be dissected cephalad for several centimeters to allow posterior positioning without tension. If appropriate, some of the distal fistula is resected before the anastomosis to the perineal skin.

In children with a high lesion, a double-barrel colostomy is performed. This effectively separates the fecal stream from the urinary tract. It also allows the performance of an augmented pressure colostogram before repair to identify the exact position of the distal rectum and the fistula. The definitive repair or posterior sagittal anorectoplasty (PSARP) is performed at about 1 yr of age. A midline incision is made, often splitting the coccyx and even the sacrum. Using a muscle stimulator, the surgeon stays strictly in the midline and divides the sphincter complex and identifies the rectum. The rectum is then opened in the midline and the fistula is identified from within the rectum. This allows a division of the fistula without injury to the urinary tract. The rectum is then dissected proximally until enough length is gained to suture it to an appropriate perineal position. The muscles of the sphincter complex are then sutured around (and especially behind) the rectum.

Other operative approaches (such as an anterior approach) are used, but the most popular procedure is by laparoscopy. This operation allows division of the fistula under direct visualization and identification of the sphincter complex by transillumination of perineum. Other imaging techniques in the management of anorectal malformations include 3D endorectal ultrasound, intraoperative MRI and colonoscopy-assisted PSARPs, which may help perform a technically “better” operation. None of these other procedures or innovations has demonstrated improved outcomes.

A similar procedure can be done for female high anomalies with variations to deal with separating the vagina and rectum from within the cloacal stem. When the stem is longer than 3 cm, this is an especially difficult and complex procedure.

Usually, the colostomy can be closed 6 wks or more after the PSARP. Two weeks after any anal procedure, twice-daily dilatations are performed by the family. By doing frequent dilatations, each one is not so painful and there is less tissue trauma, inflammation, and scarring.

**OUTCOME**

The ability to achieve rectal continence depends on both motor and sensory elements. There must be adequate muscle in the sphincter complex and proper positioning of the rectum within the complex. There must also be intact innervation of the complex and of sensory elements as well as the presence of these sensory elements in the anorectum. Patients with low lesions are more likely to achieve true continence. They are also, however, more prone to constipation, which leads to overflow incontinence. It is very important that all these patients are followed closely, and that the constipation and anal dilation are well managed until toilet training is successful. Tables 344-2 and 344-3 outline the results of continence and constipation in relation to the malformation encountered.

Children with high lesions, especially boys with rectoprostatic urethral fistulas and girls with cloacal anomalies, have a poorer chance of being continent, but they can usually achieve a socially acceptable defecation (without a colostomy) pattern with a bowel management program. Often, the bowel management program consists of a daily enema to keep the colon empty and the patient clean until the next enema. If this is successful, an antegrade continence enema (ACE) procedure, sometimes called the Malone or MACE procedure, can improve the patient’s quality of life. These procedures provide access to the right colon either by bringing the appendix out the umbilicus in a nonrefluxing fashion or by putting a plastic button in the right lower quadrant to access the cecum. The patient can then sit on the toilet and administer the enema through the ACE, thus flushing out the entire colon. Antegrade regimens can produce successful 24 hr cleanliness rates of up to 95%. Of special interest is the clinical finding that most patients improve their control with growth. Patients who wore diapers or pull-ups to primary school are often in regular underwear by high school. Some groups have taken advantage of this evidence of psychologic influences to initiate behavior modification early with good results.

### 344.2 Anal Fissure

_Begum Akay and Michael D. Klein_

Anal fissure is a laceration of the anal mucocutaneous junction. It is an acquired lesion of unknown etiology. While likely secondary to the forceful passage of a hard stool, it is mainly seen in infants younger
than 1 yr of age when the stool is frequently quite soft. Fissures may be the consequence and not the cause of constipation.

**CLINICAL MANIFESTATIONS**

A history of constipation is often described, with a recent painful bowel movement corresponding to the fissure formation after passing of hard stool. The patient then voluntarily retains stool to avoid another painful bowel movement, exacerbating the constipation, resulting in harder stools. Complaints of pain on defecation and bright red blood on the surface of the stool are often elicited.

The diagnosis is established by inspection of the perineal area. The infant’s hips are held in acute flexion, the buttocks are separated to expand the folds of the perianal skin, and the fissure becomes evident as a minor laceration. Often a small skin appendage is noted peripheral to the lesion. This “skin tag” actually represents epithelialized granulomatous tissue, formed in response to chronic inflammation. Findings on rectal examination can include hard stool in the ampulla and rectal spasm.

**TREATMENT**

The parents must be counseled as to the origin of the laceration and the mechanism of the cycle of constipation. The goal is to ensure that the patient has soft stools to avoid overstretching the anus. The healing process can take several weeks or even several months. A single episode of impaction with passing of hard stool can exacerbate the problem. Treatment requires that the primary cause of the constipation be identified. The use of dietary and behavioral modification and a stool softener is indicated. Parents should titrate the dose of the stool softener based on the patient’s response to treatment. Stool softening is best done by increasing water intake or using an oral polyethylene glycolate such as MiraLAX or GlycoLax. Surgical intervention, including stretching of the anus, “internal” anal sphincterotomy, or excision of the fissure, is not indicated or supported by scientific evidence.

Chronic anal fissures in older patients are associated with constipation, prior rectal surgery, Crohn disease, and chronic diarrhea. They are managed initially like fissures in infants, with stool softeners with the addition of sitz baths. Topical 0.2% glyceryl trinitrate reduces anal spasm and heals fissures, but it is often associated with headaches. Calcium channel blockers, such as 2% diltiazem ointment and 0.5% nifedipine cream, are more effective and cause fewer headaches than glyceryl trinitrate. Injection of botulinum toxin from 1.25-25 units is also effective and probably replicates chemically the action of internal sphincterotomy which is the most effective treatment in adults, although seldom used in children.

**CLINICAL MANIFESTATIONS**

Perianal abscess, like all skin and soft-tissue infections, have become much more common since the year 2000 (a 4-fold increase in patients admitted to our hospital, and a 3-fold increase in patients presenting to the emergency room). These usually manifest in infancy and are of unknown etiology. Fistula appears to secondary to abscess rather than a cause. Links to congenitally abnormal crypts of Morgagni have been proposed, suggesting that deeper crypts (3-10 mm rather than the normal 1-2 mm) lead to trapped debris and cryptitis (Fig. 344-4).

Conditions associated with the risk of an anal fistula include Crohn disease, tuberculosis, pilonidal disease, hidradenitis, HIV, trauma, foreign bodies, dermal cysts, sacrococcygeal teratoma, actinomycosis, lymphogranuloma venerum and radiotherapy.

The most common organisms isolated from perianal abscesses are mixed aerobic (Escherichia coli, Klebsiella pneumoniae, Staphylococcus aureus) and anaerobic (Bacteroides spp., Clostridium, Veillonella) flora. Ten percent to 15% yield pure growth of E. coli, S. aureus, or Bacteroides fragilis. There is a strong male predominance in those affected who are younger than 2 yr of age. This imbalance corrects in older patients, where the etiology shifts to associated conditions such as inflammatory bowel disease, leukemia, or immunocompromised states.

**TREATMENT**

In younger patients, symptoms are usually mild and can consist of low-grade fever, mild rectal pain, and an area of perianal cellulitis. Often these spontaneously drain and resolve without treatment. In older patients with underlying predisposing conditions, the clinical course may be more serious. A compromised immune system can mask fever and allow rapid progression to toxicity and sepsis. Abscesses in these patients may be deeper in the ischiorectal fossa or even suprlevator in contrast to those in younger patients, which are usually adjacent to the involved crypt.

Progression to fistula in patients with perianal abscesses occurs in up to 85% of cases and usually manifests with drainage from the perineal skin or multiple recurrences. Similar to abscess formation, fistulas have a strong male predominance. Histologic evaluation of fistula tracts typically reveals an epithelial lining of stratified squamous cells associated with chronic inflammation. It might also reveal an alternative etiology such as the granulomas of Crohn disease or even evidence of tuberculosis.
TREATMENT
Treatment is rarely indicated in infants with no predisposing disease because the condition is often self-limited. Even in cases of fistulization, conservative management (observation) is advocated because the fistula often disappears spontaneously. Antibiotics are not useful in these patients. When dictated by patient discomfort, abscesses may be drained under local anesthesia. Fistulas requiring surgical intervention may be treated by fistulotomy (unroofing or opening), fistulectomy (excision of the tract leaving it open to heal secondarily), or placement of a seton (heavy suture threaded through the fistula, brought out the anus and tied tightly to itself). In patients with inflammatory bowel disease topical tacrolimus has been effective.

Older children with predisposing diseases might also do well with minimal intervention. If there is little discomfort and no fever or other sign of systemic illness, local hygiene and antibiotics may be best. The danger of surgical intervention in an immunocompromised patient is the creation of an even larger, nonhealing wound. There certainly are such patients with serious systemic symptoms who require more aggressive intervention along with treatment of the predisposing condition. Broad-spectrum antibiotic coverage must be administered and wide excision and drainage are mandatory in cases involving sepsis and expanding cellulitis.

Fistulas in older patients are mainly associated with Crohn disease, a history of pull-through surgery for the treatment of Hirschsprung disease, or, in rare cases, tuberculosis. Those fistulas are often resistant to therapy and require treatment of the predisposing condition. Complications of treatment include recurrence and, rarely, incontinence.

344.4 Hemorrhoids
Begum Akay and Michael D. Klein

Hemorrhoidal disease does occur in children and adolescents, often related to a diet deficient in fiber and poor hydration. In younger children, the presence of hemorrhoids should also raise the suspicion of portal hypertension. A third of patients with hemorrhoids require treatment.

CLINICAL MANIFESTATIONS
Presentation depends on the location of the hemorrhoids. External hemorrhoids occur below the dentate line (see Figs. 344-4 and 344-5) and are associated with extreme pain and itching, often due to acute thrombosis. Internal hemorrhoids are located above the dentate line and manifest primarily with bleeding, prolapse, and occasional incarceration.

TREATMENT
In most cases, conservative management with dietary modification, decreased straining, and avoidance of prolonged time spent sitting on the toilet results in resolution of the condition. Discomfort may be treated with topical analgesics or anti-inflammatories such as Anusol (pramoxine) and Anusol-HC (hydrocortisone) and sitz baths. The natural course of thrombosed hemorrhoid involves increasing pain, which peaks at 48-72 hr, with gradual remission as the thrombus organizes and involutes over the next 1-2 wk. In cases where the patient with external hemorrhoids presents with excruciating pain soon after the onset of symptoms, thrombectomy may be indicated. This is best accomplished with local infiltration of bupivacaine 0.25% with epinephrine 1:200,000, followed by incision of the vein or skin tag and extraction of the clot. This provides immediate relief; recurrence is rare and further follow-up is unnecessary.

Internal hemorrhoids can become painful when prolapse leads to incarceration and necrosis. Pain usually resolves with reduction of hemorrhoidal tissue. Surgical treatment is reserved for patients failing conservative management. Techniques described in adults include excision, rubber banding, stapling, and excision using the LigaSure device. Given the infrequency of hemorrhoidal disease in children, and the need for general anesthesia to treat it, we have been quite satisfied with simple excision ligating the vein proximal and using the Bovie for hemostasis.

Complications are rare (<5%) and include recurrence, bleeding, infection, nonhealing wounds, and fistula formation.

344.5 Rectal Mucosal Prolapse
Begum Akay and Michael D. Klein

Rectal mucosal prolapse is the exteriorization of the rectal mucosa through the anus. In the unusual occurrence when all of the layers of the rectal wall are included, it is called procidentia or rectocele. Most cases of rectal tissue protruding through the anus are prolapse and not polyps, hemorrhoids, intussusception, or other tissue.

Most cases of prolapse are idiopathic. The onset is often between 1 and 5 yr of age. It usually occurs when the child begins standing and then resolves by approximately 3-5 yr of age when the sacrum has taken its more adult shape and the anal lumen is oriented posteriorly. Thus, the entire weight of the abdominal viscera is not pushing down on the rectum as it is earlier in development.

Other predisposing factors include intestinal parasites (particularly in endemic areas), malnutrition, diarrhea, ulcerative colitis, pertussis, Ehlers-Danlos syndrome, meningocoele (more often associated with procidentia owing to the lack of perineal muscle support), cystic fibrosis, and chronic constipation. Patients treated surgically for imperforate anus can also have varying degrees of rectal mucosal prolapse. This is particularly common in patients with poor sphincteric development.

CLINICAL MANIFESTATIONS
Rectal mucosal prolapse usually occurs during defecation, especially during toilet training. Reduction of the prolapse may be spontaneous or accomplished manually by the patient or parent. In severe cases, the prolapsed mucosa becomes congested and edematous, making it more difficult to reduce. Rectal prolapse is usually painless or produces mild discomfort. If the rectum remains prolapsed after defecation, it can be traumatized by friction with undergarments, with resultant bleeding, wetness, and potentially, ulceration. The appearance of the prolapse varies from bright red to dark red and resembles a beehive. It can be as long as 10-12 cm. See Chapter 345 for a distinction from a prolapsed polyp.
**TREATMENT**

Initial evaluation should include tests to rule out any predisposing conditions, especially cystic fibrosis and sacral root lesions. Reduction of protrusion is aided by pressure with warm compresses. An easy method of reduction is to cover the finger with a piece of toilet paper, introduce it into the lumen of the mass, and gently push it into the patient's rectum. The finger is then immediately withdrawn. The toilet paper adheres to the mucous membrane, permitting release of the finger. The paper, when softened, is later expelled.

Conservative treatment consists of careful manual reduction of the prolapse after defecation, attempts to avoid excessive pushing during bowel movements (with patient's feet off the floor), use of laxatives and stool softeners to prevent constipation, avoidance of inflammatory conditions of the rectum, and treatment of intestinal parasitosis when present. If all this fails, surgical treatment may be indicated. Existing surgical options are associated with some morbidity, and therefore medical treatment should always be attempted first.

Sclerosing injections have been associated with complications such as neurogenic bladder. We have found linear cauterization effective and with few complications other than recurrence. In the operating room, the prolapse is recreated by traction on the mucosa. Linear burns are made through nearly the full thickness of the mucosa using electrocautery. One can usually make 8 linear burns on the outside and 4 on the inside of the prolapsed mucosa. In the immediate postoperative period, prolapse can still occur, but in the next several weeks, the burned areas contract and keep the mucosa within the anal canal. The Delorme mucosal sleeve resection addresses mucosal prolapse via a transanal approach by incising, prolapsing, and amputating the redundant mucosa. The resulting mucosal defect is then approximated with absorbable suture.

For patients with procidentia or full-thickness prolapse or intussusception of the rectosigmoid (usually from myelodysplasia or other sacral root lesions) other, more invasive options exist. Those most commonly in use by pediatric surgeons today include the following: A modification of the Thiersch procedure involves placing a subcutaneous suture to narrow the anal opening. Complications include obstruction, fecal impaction, and fistula formation. Laparoscopic rectopexy is effective and can be performed as an outpatient. The Altemeier perineal rectosigmoidectomy is a transanal, full-thickness resection of redundant bowel with a primary anastomosis to the anus.

**344.6 Pilonidal Sinus and Abscess**

Begum Akay and Michael D. Klein

The etiology of pilonidal disease remains unknown; 3 hypotheses explaining its origin have been proposed. The first states that trauma, such as can occur with prolonged sitting, impacts hair into the subcutaneous tissue, which serves as a nidus for infection. The second suggests that in some patients, hair follicles exist in the subcutaneous tissues, perhaps the result of some embryologic abnormality, and that they serve as a focal point for infection, especially with secretion of hair oils. The third speculates that motion of the buttocks disturbs a particularly deep midline crease and works bacteria and hair beneath the skin. This theory arises from the apparent improved short-term and long-term results of operations that close the wound off the midline, obliterating the deep natal cleft.

Pilonidal disease usually manifests in adolescents or young adults with significant hair over the midline sacral and coccygeal areas. It can occur as an acute abscess with a tender, warm, indurated, erythematous swelling or as draining sinus tracts. This disease does not resolve with nonoperative treatment. An acute abscess should be drained and packed open with appropriate anesthesia. Oral broad-spectrum antibiotics covering the usual isolates (S. aureus and Bacteroides species) are prescribed, and the patient's family withdraws the packing over the course of a week. When the packing has been totally removed, the area can be kept clean by a bath or shower. The wound usually heals completely in 6 wk. Once the wound is healed, most pediatric surgeons feel that elective excision should be scheduled to avoid recurrence. There are some reports, however, this is only necessary if the disease recurs. Usually, patients who present with sinus tracts are managed with a single elective excision.

Most surgeons carefully identify the extent of each sinus tract and excise all skin and subcutaneous tissue involved to the fascia covering the sacrum and coccyx. Some close the wound in the midline; others leave it open and packed for healing by secondary intention. This method has been modified by the application of a vacuum-assisted (VAC sponge) dressing. This is a system that applies continuous suction to a porous dressing. It is usually changed every 3 days and can be done at home with the assistance of a nurse. Some marsupialize the wound by suturing the skin edges down to the exposed fascia covering the sacrum and coccyx. There appears to be improved success with excision and closure in such a way that the suture line is not in the midline. Currently there appears to be enthusiasm for less radical methods that Bascon has introduced, treating simple sinus tracts with small local procedures and limiting excision to only diseased tissues, while still keeping the incision off the midline. Recurrence or wound-healing problems are relatively common, occurring in 9-27% of cases. The variety of treatments and procedures currently being described indicates that all of them are associated with significant complications and delays in return to normal activity. Still, it is rare for problems to persist beyond 1-2 yr. Recalcitrant cases are treated by a large, full-thickness gluteal flap or skin grafting.

A simple dimple located in the midline intergluteal cleft, at the level of the coccyx, is seen relatively commonly in normal infants. No evidence indicates that this little sinus provokes any problems for the patient. An open dermal sinus is an asymptomatic, benign condition that does not require operative intervention.
Chapter 344  Surgical Conditions of the Anus and Rectum[Page 45]

Bibliography

Tumors of the digestive tract in children are mostly polypoid. They are also commonly syndromic tumors and tumors with known genetic identification (Table 345-1). They usually manifest as painless rectal bleeding, but they can serve as lead points for intussusception. Most intestinal tumors can be generally classified into 2 groups: hamartomatous or adenomatous.

**HAMARTOMATOUS TUMORS**

Hamartomas are benign tumors composed of tissues that are normally found in an organ but that are not organized normally. Juvenile, retention, or inflammatory polyps are hamartomatous polyps, which represent the most common intestinal tumors of childhood, occurring in 1-2% of children. Patients generally present in the 1st decade, most often at ages 2-5 yr, and rarely at younger than 1 year. Polyps may be found anywhere in the gastrointestinal (GI) tract, most commonly in the colon or rectum; they are often solitary but may be multiple.

Histologically, juvenile polyps are composed of hamartomatous collections of mucus-filled glandular and stromal elements with inflammatory infiltrate, covered with a thin layer of epithelium. These polyps are often bulky, vascular, and prone to bleed as their growth exceeds their blood supply with resultant mucosal ulceration, or autoamputation with bleeding from a residual central artery.

AV, Arteriovenous; CHRPE, congenital hypertrophy of the retinal pigment epithelium; GI, gastrointestinal.

Patients often present with painless rectal bleeding after defecation. Bleeding is generally scant and intermittent; rarely iron deficiency anemia is the chief presenting symptom. Extensive bleeding can occur but is generally self-limited, requiring supportive care until the bleeding stops spontaneously after autoamputation. Occasionally endoscopic polypectomy is required for control of bleeding. Abdominal pain or cramps are uncommon unless associated with intussusception. Patients can present with prolapse, with a dark, edematous, pedunculated mass protruding from the rectum. Mucus discharge and pruritus are associated with prolapse.

Patients presenting with rectal bleeding require thorough work-up; differential diagnosis includes anal fissure, other intestinal polyposis syndromes, Meckel diverticulum, inflammatory bowel disease, intestinal infections, Henoch-Schönlein purpura, or coagulopathy.

Diagnosis and therapy are best accomplished via endoscopy. Polyps may be visualized via air-contrast barium enema, but this provides no therapeutic advantage and is uncomfortable and usually performed without sedation or anesthesia. Colonoscopy affords opportunity for biopsy, polypectomy by snare cautery, and visualization of synchronous lesions; up to 50% of children have 1 or more additional polyps, and approximately 20% may have more than 5 polyps. Retrieved polyps should be sent for histologic evaluation for definitive diagnosis.

**Juvenile Polyposis Syndrome**

Patients with juvenile polyposis syndrome (JPS) present with multiple juvenile polyps, ≥5 but typically 50-200. Polyps may be isolated to the colon or distributed throughout the GI tract. There is often a family history (20-50%) with an autosomal dominant pattern of variable penetrance. Alterations in transforming growth factor-β pathways have been identified in some JPS patients and families; mutations in SMAD4 or BMPR1A are found in 50-60% of patients with JPS. Genetic testing is available for both of these mutations. Clinical diagnosis of JPS is established by presence of 1 of the following: 3-10 polyps on colonoscopy; polyps outside the colon; or any number of polyps in a patient with a family history of JPS.

Histologically, these polyps are identical to solitary juvenile polyps; however, the GI malignancy risk is greatly increased (10-50%). Most malignancy is colorectal, although gastric, upper GI, and pancreatic tumors have been described. The risk of malignancy is greater in patients with >3 polyps and a positive family history. These patients...
should therefore undergo routine esophagogastroduodenoscopy, colonoscopy, and upper GI contrast studies. Serial polypectomy or polyp biopsy should be undertaken if possible. If dysplasia or malignant degeneration is found, a total colectomy is indicated.

Juvenile polyposis of infancy is characterized by early polyposis formation (younger than 2 yr of age) and may be associated with protein-losing enteropathy, hypoproteinemia, anemia, failure to thrive, and intussusception. Early endoscopic or surgical intervention may be needed.

**Peutz-Jeghers Syndrome**

Peutz-Jeghers syndrome (PJS) is a rare autosomal dominant disorder (incidence: ~1:120,000 total population) characterized by mucocutaneous pigmentation and extensive GI hamartomatous polyposis. Macular pigmented lesions may be dark brown to dark blue and are found primarily around the lips and oral mucosa, although these lesions may also be found on the hands, feet, or perineum. Lesions can fade by puberty or adulthood.

Polyps are primarily found in the small intestine (in order of prevalence: jejunum, ileum, duodenum) but may also be colonic or gastric. Histologically, polyps are defined by normal epithelium surrounding bundles of smooth muscle arranged in a branching or frondlike pattern. Symptoms arising from GI polyps in PJS are similar to those of other polyposis syndromes, namely bleeding and abdominal cramping from obstruction or recurrent intussusception. Patients can require repeated laparotomies and intestinal resections.

The diagnosis of PJS is made clinically in patients with histologically proven hamartomatous polyps if 2 of 3 conditions are met: positive family history with an autosomal dominant inheritance pattern, mucocutaneous hyperpigmentation, and small bowel polyposis. Genetic testing can reveal mutations in **LKB1/STK11** (19p13.3), a serine-threonine kinase that acts as a tumor-suppressor gene. Up to 94% of patients with clinical characteristics of PJS have a mutation at this locus. Only 50% of patients with PJS have an affected family member, suggesting a high rate of spontaneous mutations.

Patients with PJS have increased risk of GI and extraintestinal malignancies. Lifetime cancer risk has been reported from 47-93%. Colorectal, breast, and reproductive tumors are most common. GI surveillance should begin in childhood (by age 8 yr or when symptoms occur) with upper and lower endoscopy. The small bowel may be evaluated radiographically, with enteroscopy, or with wireless capsule endoscopy. Polyps larger than 1.5 cm should be removed. Screening for breast, gynecologic, and testicular cancers should be routine after diagnosis. Polyps larger than 1.5 cm should be removed. Screening for breast, gynecologic, and testicular cancers should be routine after diagnosis. Polyps larger than 1.5 cm should be removed. Screening for breast, gynecologic, and testicular cancers should be routine after diagnosis.

The clinical presentation of FAP is variable. Polyps are generally asymptomatic initially (and might remain so). If symptoms develop, they can include rectal bleeding (possibly with secondary anemia), cramping, and diarrhea. The presence of symptoms at presentation does not correlate with malignant changes. Diagnosis should be suspected from family history, and ensuing sigmoidoscopy or colonoscopy is confirmatory. Histologic examination of biopsied polyps reveals adenomatous architecture (as opposed to inflammatory or hamartomatous polyps found in other polyposis syndromes) with varying degrees of dysplasia. Genetic testing for APC mutations is clinically available, and index patients should be tested. If a mutation is identified, affected family members should be screened and appropriate genetic counseling should be provided. If the index patient does not demonstrate a defined mutation, family members may undergo genetic testing, which might identify novel APC mutations. Children with identified APC mutations must undergo careful surveillance, with sigmoidoscopy every 1-2 yr. Once polyps are identified, colonoscopy should be performed annually. Patients should also have upper endoscopy after development of colonic polyps to monitor for gastric and especially duodenal lesions.

Treatment of FAP requires prophylactic proctocolectomy to prevent cancer. Ileoanal pull-through procedures restore bowel continuity, with acceptable functional outcomes. Resection should be done once polyposis has become extensive (>20-30) or by the mid-teens. Nonsteroidal antiinflammatory agents, such as sulindac, and cyclooxygenase-2 inhibitors, such as celecoxib, might inhibit polyp progression. No guidelines have been established, however, and their efficacy in preventing malignant transformation of existing polyps is unknown.

**Carcinoma**

Primary carcinomas of the small bowel or colon are extremely rare in children. Development of adenocarcinoma in adolescence or early
adolescence. Patients may be asymptomatic or can present with abdominal pain, constipation, and vomiting. Delay in diagnosis is common. Many patients present with advanced-stage disease, with microscopic or gross metastases at the time of diagnosis. Surgical resection is the primary treatment modality, although with delayed presentation and advanced-stage disease, complete resection may not be possible. Chemotherapy and radiation have a limited role in patients with metastatic disease.

**OTHER GASTROINTESTINAL TUMORS**

**Lymphoma**

Lymphoma is the most common GI malignancy in the pediatric population. Approximately 30% of children with non-Hodgkin lymphoma present with abdominal tumors. Immunocompromised patients have an increased incidence of lymphoma. Predisposing conditions include HIV/AIDS, agammaglobulinemia, long-standing celiac disease, and bone marrow or solid-organ transplantation. Lymphoma can occur anywhere in the GI tract, but it most commonly occurs in distal small bowel and ileocecal region. Presenting symptoms include crampy abdominal pain, vomiting, obstruction, bleeding, or palpable mass. Lymphoma should be considered in patients older than 3 yr of age who present with intussusception.

**Nodular Lymphoid Hyperplasia**

Lymphoid follicles in the lamina propria and submucosa of the gut normally aggregate in Peyer patches, most prominently in the distal ileum. These follicles can become hyperplastic, forming nodules that protrude into the lumen of the bowel. Some suggested etiologies are infectious (classically *Giardia*), allergic, or immunologic. Nodular lymphoid hyperplasia has been described in infants with enterocolitis secondary to dietary protein sensitivity. This phenomenon has also been described in patients with inflammatory bowel disease and Castleman disease. Patients may be asymptomatic or may present with abdominal pain, rectal bleeding, diarrhea, or intussusception. Nodular lymphoid hyperplasia usually resolves spontaneously and rarely requires therapy; in cases with severe pain or bleeding, corticosteroids may be effective.

**Carcinoid Tumor**

Carcinoids are neuroendocrine tumors of enterochromaffin cells, which can occur throughout the GI tract, but in children they are typically found in the appendix. This is often an incidental diagnosis at the time of appendectomy. Complete resection of small tumors (<1 cm) with clear surgical margins is curative. Appendiceal tumors >2 cm mandate further bowel resection. Carcinoid tumors outside the appendix (small intestine, rectum, stomach) are more likely to metastasize. Metastatic carcinoid tumor within the liver can give rise to the carcinoid syndrome. Serotonin, 5-hydroxytryptophan, or histamine are elaborated by the tumor, and elevated serum levels cause cramps, diarrhea, vasomotor disturbances (flushing), bronchoconstriction, and right-heart failure. The diagnosis is confirmed by elevated urinary 5-hydroxyindolacetic acid. Symptomatic relief of carcinoid symptoms may be achieved with administration of somatostatin analogs (octreotide).

**Leiomyoma**

Leiomyomas are rare benign tumors that can arise anywhere in the GI tract, although most often in the stomach, jejunum, or distal ileum. Age of presentation is variable, from the newborn period through adolescence. Patients may be asymptomatic or can present with an abdominal mass, obstruction, intussusception, volvulus, or pain and bleeding from central necrosis of the tumor. Surgical resection is the treatment of choice. Pathologically, these tumors may be difficult to distinguish from malignant leiomyosarcomas. Smooth muscle tumors occur with increased incidence in children with HIV or those requiring immunosuppression after transplantation.

**Gastrointestinal Stromal Cell Tumors**

Gastrointestinal stromal cell tumors (GISTs) are intestinal mesenchymal tumors that probably arise from interstitial cells of Cajal or their precursors. Historically, these may have been diagnosed as tumors of smooth muscle or neural cell origin. The World Health Organization recognized GIST in 1990 as a distinct neoplasm. Typically GISTs arise in adults, after the 3rd decade of life. Cases have also been reported in the pediatric population, generally in adolescents. In the pediatric population tumors are most commonly found in the stomach, though they can occur anywhere in the GI tract or even the mesentery or omentum. Patients may be asymptomatic or can present with an abdominal mass, lower GI bleeding, or obstruction. Treatment consists of surgical en bloc resection of local disease. Recurrence rates are high and early postoperative surveillance is recommended. GISTs occurring in adults are typically associated with mutation in the KIT oncogene. This mutation is less commonly found in pediatric GISTs (~15%). Adjuvant therapy for KIT+ lesions is imatinib or sunitinib, tyrosine kinase inhibitors that are available as oral therapy. Patients with persistent disease or metastases might benefit from treatment.

**Vascular Tumors**

Vascular malformations and hemangiomas are rare in children. The usual presentation is painless rectal bleeding, which may be chronic or acute, with massive or even fatal hemorrhage. There are usually no associated symptoms, although intussusception has been described. Half of patients have associated cutaneous hemangiomas or telangiectasias. These lesions may be associated with blue rubber bleb nevus syndrome or hereditary hemorrhagic telangiectasia. About half of these lesions are in the colon and can be identified on colonoscopy. During acute bleeding episodes, bleeding can be localized via nuclear medicine bleeding scans, mesenteric angiography, or endoscopy. Colonic bleeding may be controlled by endoscopic means. Surgical intervention is required only occasionally for isolated lesions.

Bibliography
Inguinal hernias are one of the most common conditions seen in pediatric practice and the most common surgical procedure performed in pediatric surgical practice. The frequency of this condition in concert with its potential morbidity of ischemic injury to the intestine, testis, or ovary makes proper diagnosis and management an important part of daily practice for pediatric practitioners and pediatric surgeons. The overwhelming majority of inguinal hernias in infants and children are congenital indirect hernias (99%) as a consequence of a patent processus vaginalis (PV); a developmental structure important in testicular descent. The incidence of inguinal hernia in children is up to 10 times higher in boys than in girls. Two other types of inguinal hernia are direct (acquired) hernia (0.5-1.0%) and femoral hernia (<0.5%). Approximately 50% of inguinal hernias manifest clinically in the 1st yr of life, most in the 1st 6 mo. Premature infants have an incidence of
Inguinal hernia approaching 30%. The risk of incarceration and possible strangulation of an inguinal hernia is also greatest in the 1st yr of life (30-40%) and mandates prompt identification and operative repair to minimize morbidity and complications.

**EMBRYOLOGY AND PATHOGENESIS**

Indirect inguinal hernias in infants and children are congenital and result from an arrest of embryologic development; failure of obliteration of the PV rather than a weakness in the inguinal musculature. The pertinent developmental anatomy of indirect inguinal hernia relates to development of the gonads and descent of the testis through the inguinal ring and into the scrotum late in gestation. The testes descend from the urogenital ridge in the retroperitoneum to the area of the internal ring by about 28 wk of gestation. The final descent of the testes into the scrotum occurs late in gestation between weeks 28 and 36. The testis is preceded in descent to the scrotum by the gubernaculum and the PV. The PV, an outpouring of peritoneum in the lower abdomen, is present in the developing fetus at 12 wk gestation that develops lateral to the deep inferior epigastric vessels and descends anteriorly along the spermatic cord within the cremasteric fascia through the internal inguinal ring. The testis accompanies the PV as it exits the abdomen and descends into the scrotum. The gubernaculum testis forms from the mesonephros (developing kidney), attaches to the lower pole of the testis, and directs the testis through the internal ring, inguinal canal and into the scrotum. The testis passes through the inguinal canal in a few days but takes about 4 wk to migrate from the external ring to the scrotum. The cord-like structures of the gubernaculum occasionally pass to ectopic locations (perineum or femoral region), resulting in ectopic testes.

In the last few weeks of gestation or shortly after birth, the layers of the PV normally fuse together and obliterate the patent PV. The layers of the PV normally fuse together and obliterate the PV rather than a weakness in the inguinal musculature. Failure of the PV to close permits fluid or abdominal viscera to escape the peritoneal cavity through the inguinal canal to the testis. The PV also obliterates just above the testis, and the portion of the PV that envelops the testis becomes the tunica vaginalis. In girls, the PV obliterates earlier, at approximately 7 mo of gestation, and may explain why girls demonstrate a much lower incidence of inguinal hernia. Failure of the PV to close permits fluid or abdominal viscera to escape the peritoneal cavity through the extraperitoneal inguinal canal and accounts for a variety of inguinal–scrotal abnormalities seen in infancy and childhood. The ovaries descend into the pelvis from the urogenital ridge but do not exit from the abdominal cavity. The cranial portion of the gubernaculum in girls differentiates into the ovarian ligament, and the inferior aspect of the gubernaculum becomes the round ligament, which passes through the internal ring and attaches to the labia majora. The PV in girls extends into the labia majora through the inguinal canal and is also known as the canal of Nuck. Involution of the left-sided PV precedes that of the right; which is consistent with the increased incidence of indirect inguinal hernias on the right side (60%).

Androgenic hormones, adequate end-organ receptors, and mechanical factors such as increased intra-abdominal pressure influence complete descent of the testis through the inguinal canal. The testes and spermatic cord structures (spermatic vessels and vas deferens) are located in the retroperitoneum but are affected by increases in intra-abdominal pressure as a consequence of their intimate attachment to the descending PV. The genitofemoral nerve also has an important role: It innervates the cremaster muscle, which develops within the gubernaculum, and experimental division or injury to both nerves in the fetus prevents testicular descent. Failure of regression of smooth muscle (present to provide the force for testicular descent) might have a role in the development of indirect inguinal hernias. Several studies have investigated genes involved in the control of testicular descent for their role in closure of the patent PV, for example, hepatocyte growth factor and calcitonin gene-related peptide. Unlike in adult hernias, there does not appear to be any change in collagen synthesis associated with inguinal hernias in children (Fig. 346-1).

A direct inguinal hernia originates medial to the deep inferior epigastric vessels and is external to the cremasteric fascia; the hernia sac directly through the posterior wall of the inguinal canal. A femoral hernia originates medial to the femoral vein and descends inferior to the inguinal ligament along the femoral canal.

**GENETICS**

There is some genetic risk incurred for siblings of patients with inguinal hernias; the sisters of affected girls are at the highest risk, with a relative risk of 17.8. In general, the risk of brothers of a sibling is approximately 4-5, as is the risk of a sister of an affected brother. Both a multifactorial threshold model and autosomal dominance with incomplete penetrance and sex influence have been suggested as an explanation for this pattern of inheritance.

**PATHOLOGY**

Failure of closure of the PV leads to a number of common inguinal–scrotal conditions in infants and children including: inguinal hernia, scrotal hydrocele (communicating and noncommunicating), and hydrocele of the spermatic cord. Closure of the PV is often incomplete at birth and continues postnatally; the rate of patency is inversely proportional to the age of the child. It has been estimated that the patency rate of the PV is as high as 80% at birth and decreases to ≈40% during the 1st yr of life, and that ≈20% of boys have a persistent patency of the PV at 2 yr of age. Patency of the PV after birth is an opening of the abdominal cavity to the inguinal region and therefore a potential hernia, but not all patients will develop a clinical hernia. An inguinal hernia occurs clinically when intraabdominal contents escape...
The incidence of congenital indirect inguinal hernia in full-term newborn infants is estimated at 3.5-5.0%. The incidence of hernia in preterm and low birthweight infants is considerably higher, ranging from 9-11%, and approaches 30% in very-low birthweight infants (<1,000 g) and preterm infants (<28 wk of gestation). Inguinal hernia is much more common in boys than girls, with a male:female ratio of approximately 8:1. Approximately 60% of inguinal hernias occur on the right side, 30% are on the left side, and 10% are bilateral. The incidence of bilateral hernias is higher in girls and appears to be 20-40%. An increased incidence of congenital inguinal hernia has been documented in twins and in family members of patients with inguinal hernia. There is a history of another inguinal hernia in the family in 11.5% of patients.

**CLINICAL PRESENTATION**

An inguinal hernia typically appears as a bulge or mass in the inguinal region. In boys, the mass potentially extends through the inguinal area into the scrotum; in girls the mass typically occurs in the upper portion of the labia majora. The bulge or mass is most visible at times of irritability or increased intraabdominal pressure (crying, straining, coughing). It may be present at birth or might not appear until weeks, months, or years later. The bulge is most often first noted by the parents or on routine examination by the primary care physician. The classic history from the parents is of intermittent groin, labial, or scrotal swelling that spontaneously reduces but that is gradually enlarging or is more persistent and is becoming more difficult to reduce. The hallmark signs of an inguinal hernia on physical examination are a smooth, firm mass that emerges through the external inguinal ring lateral to the pubic tubercle and enlarges with increased intraabdominal pressure. When the child relaxes, the hernia typically reduces spontaneously or can be reduced by gentle pressure, first posteriorly to free it from the external ring and then upward toward the peritoneal cavity. In boys, the hernia sac contains intestines; female infants often have an ovary and fallopian tube in the hernia sac.

Methods used to demonstrate the hernia on examination vary depending on the age of the child. A quiet infant can be made to strain the abdominal muscles by stretching the infant out supine on the bed with legs extended and arms held straight above the head. Most infants struggle to get free, thus increasing the intraabdominal pressure and pushing out the hernia. Older patients can be asked to perform the Valsalva maneuver by blowing up a balloon or coughing. The older child should be examined while standing and examination after voiding also can be helpful. With increased intraabdominal pressure, the protruding mass is obvious on inspection of the inguinal region or can be palpated by an examining finger invaginating the scrotum to palpate at the external ring. Another test is the "silk glove sign," which describes the feeling of the layers of the hernia sac as they slide over the spermatic cord structures with rolling of the spermatic cord beneath the index finger at the pubic tubercle. A femoral hernia appears as a protrusion on the medial aspect of the thigh, below the inguinal region and does not enter the scrotum or labia. In the absence of a bulge, the finding of increased thickness of the inguinal canal structures on palpation also suggests the diagnosis of an inguinal hernia. It is important on examination to note the position of the testes because retracted testes are common in infants and young boys and can mimic an inguinal hernia with a bulge in the region of the external ring. Because in the female patient approximately 20-25% of inguinal hernias are sliding hernias (the contents of the hernia sac are adherent within the sac and therefore not reducible), a fallopian tube or ovary can be palpated in the inguinal canal as a firm, slightly mobile, nontender mass in the labia or inguinal canal.

As the majority of young child hernias reduce spontaneously, the physical examination in the office can be equivocal. Infants and children with a strong history suggestive of inguinal hernia and an equivocal clinical examination may be offered ultrasound or referral to a pediatric surgeon. In recent years, diagnostic laparoscopy has been increasingly used to evaluate for suspected inguinal hernia; particularly in infants where the risk of incarceration and potential injury to the intestines or testis is high. In an older child with low risk of

incarceration, the parents can be educated and asked to observe for the bulge and take a digital image at home.

**EVALUATION OF ACUTE INGUINAL–SCROTAL SWELLING**

Commonly in pediatric practice, an inguinal–scrotal mass appears suddenly in an infant or child and is associated with discomfort. The **differential diagnosis** includes incarcerated inguinal hernia, acute hydrocele, torsion of an undescended testis, and suppurative inguinal lymphadenitis. Differentiating between the incarcerated inguinal hernia and the acute hydrocele is probably the most difficult. The infant or child with an incarcerated inguinal hernia is likely to have associated findings suggesting intestinal obstruction, such as colicky abdominal pain, abdominal distention, vomiting, and cessation of stool, and might appear ill. The infant with an acute hydrocele might have discomfort but is consolable and tolerates feedings without signs or symptoms suggesting intestinal obstruction. When the diagnosis is incarcerated inguinal hernia, plain radiographs typically demonstrate distended intestines with multiple air–fluid levels.

On examination of the child with the acute hydrocele, the clinician may note that the mass is somewhat mobile. In addition, in the area between the suspected hydrocele mass and the internal ring, the cord structures can appear only slightly thickened. With the incarcerated hernia, there is a lack of mobility of the groin mass and marked swelling or mass extending from the scrotal mass through the inguinal area and up to and including the internal ring. An experienced clinician can selectively use a bimanual examination to help differentiate groin abnormalities. The examiner palpates the internal ring per rectum, with the other hand placing gentle pressure on the inguinal region over the internal ring. In cases of an indirect inguinal hernia, an intraabdominal organ can be palpated extending through the internal ring.

Another method used in evaluation is **transillumination**. It must be noted that transillumination can be misleading because the thin wall of the infant’s intestine can approximate that of the hydrocele wall and both might transilluminate. This is also the reason aspiration to determine the contents of a groin mass is discouraged. **Ultrasoundography** can help distinguish between a hernia, a hydrocele, and lymphadenopathy. An expeditious diagnosis is important to avoid the potential complications of an incarcerated hernia, which can develop rapidly. Diagnostic laparoscopy has emerged as an effective and reliable tool in this setting by pediatric surgeons but requires general anesthesia.

The occurrence of suppurative adenopathy in the inguinal region can be confused with an incarcerated inguinal hernia. Examination of the watershed area of the inguinal lymph node might reveal a superficial infected or crusted lesion. In addition, the swelling associated with inguinal lymphadenopathy is typically located more inferior and lateral than the mass of an inguinal hernia, and there may be other associated enlarged nodes in the area. Torsion of an undescended testis can manifest as a painful erythematous mass in the groin. The absence of a gonad in the scrotum in the ipsilateral side should clinch this diagnosis.

**Incarcerated Hernia**

**Incarceration** is a common consequence of untreated inguinal hernia in infants and presents as a nonreducible mass in the inguinal canal, scrotum, or labia. Contained structures can include small bowel, appendix, omentum, colon, or, rarely, Meckel diverticulum. In girls, the ovary, fallopian tube, or both are commonly incarcerated. Rarely, the uterus in infants can also be pulled into the hernia sac. A **strangulated hernia** is one that is tightly constricted in its passage through the inguinal canal and, as a result, the hernia contents have become ischemic or gangrenous.

Although incarceration may be tolerated in adults for years, most nonreducible inguinal hernias in children, unless treated, rapidly progress to strangulation with potential infarction of the hernia contents or intestinal obstruction. Initially, pressure on the herniated viscera leads to impaired lymphatic and venous drainage. This leads, in turn, to swelling of the herniated viscera, which further increases the compression in the inguinal canal, ultimately resulting in total occlusion of the arterial supply to the trapped viscera. Progressive ischemic changes take place, culminating in gangrene and/or perforation of the herniated viscera. The testis is at risk of ischemia because of compression of the testicular blood vessels by the strangulated hernia. In girls, herniation of the ovary places it at risk of strangulation and torsion. The incidence of incarceration of an inguinal hernia is between 12% and 17% throughout childhood; two-thirds of incarcerated hernias occur in the 1st yr of life. The greatest risk is in infants younger than 6 mo of age, with reported incidences of incarceration between 25% and 30%. The incidence of incarceration is slightly less in premature infants, although the reasons are unclear.

The symptoms of an incarcerated hernia are irritability, feeding intolerance, and abdominal distention in the infant; pain in the older child. Within a few hours, the infant becomes inconsolable; lack of flatus or stool signals complete intestinal obstruction. A somewhat tense, nonfluctuant mass is present in the inguinal region and can extend down into the scrotum or labia. The mass is well defined, firm, and does not reduce. With the onset of ischemic changes, the pain intensifies, and the vomiting becomes bilious or feculent. Blood may be noted in the stools. The mass is typically tender, and there is often edema and erythema of the overlying skin. The testes may be normal, demonstrate a reactive hydrocele, or may be swollen and hard on the affected side because of venous congestion resulting from compression of the spermatic veins and lymphatic channels at the inguinal ring by the tightly strangulated hernia mass. Abdominal radiographs demonstrate features of partial or complete intestinal obstruction, and gas within the incarcerated bowel segments may be seen below the inguinal ligament or within the scrotum.

**Ambiguous Genitalia**

Infants with disorders of sexual development commonly present with inguinal hernias, often containing a gonad, and require special consideration. In female infants with inguinal hernias, particularly if the presentation is bilateral inguinal masses, **testicular feminization syndrome** should be suspected (>50% of patients with testicular feminization have an inguinal hernia) (see Chapter 588). Conversely, the true incidence of testicular feminization in all female infants with inguinal hernias is difficult to determine but is approximately 1%. In phenotypic females, if the diagnosis of testicular feminization is suspected preoperatively, the child should be screened with a buccal smear for Barr bodies and appropriate genetic evaluation before proceeding with the hernia repair. The diagnosis of testicular feminization is occasionally made at the time of operation by identifying an abnormal gonad (testis) within the hernia sac or absence of the uterus on laparoscope or rectal exam. In the normal female infant, the uterus is easily palpated as a distinct midline structure beneath the symphysis pubis on rectal examination. Preoperative diagnosis of testicular feminization syndrome or other disorders of sexual development such as mixed gonadal dysgenesis and selected pseudohermaphrodites enables the family to receive genetic counseling, and gonadectomy can be accomplished at the time of the hernia repair.

**MANAGEMENT**

The presence of an inguinal hernia in the pediatric age group constitutes the indication for operative repair. An inguinal hernia does not resolve spontaneously, and early repair eliminates the risk of incarceration and the associated potential complications, particularly in the 1st 6-12 mo of life. The timing of operative repair depends on several factors, including age, general condition of the patient, and comorbid conditions. In infants (younger than 1 yr old) with an inguinal hernia, repair should proceed promptly (within 2-3 wk) because as many as 70% of incarcerated inguinal hernias requiring emergency operation occur in infants younger than 11 mo. In addition, the incidence of complications associated with **elective hernia repair** (intestinal injury, testicular atrophy, recurrent hernia, wound infection) are low (<1%), but rise to as high as 18-20% when repair is performed at the time of
incarceration. The incidence of testicular atrophy after incarceration in infants younger than 3 mo of age has been reported as high as 30%. Therefore, an approach emphasizing prompt elective repair in infants is warranted. In children older than 1 yr, the risk of incarceration is less and the repair can be scheduled with less urgency. For the routine reducible hernia, the operation should be carried out electively shortly after diagnosis. Elective inguinal hernia repair can be safely performed in an outpatient setting with an expectation for full recovery within 48 hr. The operation should be performed at a facility with the ability to admit the patient to an inpatient unit as needed. Certain conditions can dictate postponement of repair, such as marked prematurity, intercurrent pneumonia (especially respiratory syncytial virus), other infections, or severe congenital heart disease. In cases of prematurity (1,800–2,000 g), repair is typically performed before discharge from the neonatal ICU.

The operation is most often performed under general anesthesia, but it can be performed under spinal anesthesia in selected high-risk infants in whom avoidance of intubation is preferable (because of, e.g., chronic lung disease or bronchopulmonary dysplasia). A regional caudal block or local inguinal nerve block using local anesthetic is useful to diminish perioperative pain and increase patient comfort. These techniques, along with the use of rapid-acting general anesthetics, allow the majority of infants to be discharged home within hours of operation. Prophylactic antibiotics are not routinely used except for associated conditions, such as congenital heart disease or the presence of a ventriculoperitoneal shunt. Preterm infants mandate special consideration because of their higher risk for apnea and bradycardia following general anesthesia (see Chapter 61). Infants younger than 44 wk postconceptional age and full-term infants younger than 3 mo of age and with comorbid conditions should be observed overnight with appropriate apnea and cardiorespiratory monitors.

An incarcerated, irreducible hernia without evidence of strangulation in a clinically stable patient should initially be managed nonoperatively. Unless there is clear peritonitis or bowel compromise, incarcerated hernias can usually be reduced manually using a technique called *taxis*. Manual reduction is performed first with traction caudad and posteriorly to free the mass from the external inguinal ring, and then upward to reduce the contents back into the peritoneal cavity. The attempt should not be continued if the infant is crying and resisting the pressure on the hernia. The use of cautious sedation or analgesia with experienced monitoring before attempting reduction can be helpful; this reduces intraabdominal pressure and relieves the pressure on the neck of the hernia sac at the inguinal ring. Care must be taken to avoid respiratory depression, especially common in the premature infant. Other techniques advocated to assist in the nonoperative reduction of an incarcerated inguinal hernia include elevation of the lower torso and legs. Ice packs should be avoided in infants because of the risk of hypothermia but may be used for brief periods in the older child. If reduction is successful but difficult, the patient should be observed (several hours) to ensure that feedings are tolerated and there is no concern that necrotic intestine was reduced; fortunately, this is an uncommon occurrence. Because of the high risk for early recurrent incarceration, surgical repair is performed 24-48 hr later, by which time there is less edema, handling of the sac is easier, and the risk of complications is reduced.

A common presentation in female patients is an irreducible ovary in the inguinal hernia in an otherwise asymptomatic patient. The inguinal mass is soft and nontender to gentle exam, and there is no swelling or edema; thus, there are no findings suggesting strangulation. This represents a “sliding” hernia with the fallopian tube and ovary fused to the wall of the hernia sac. Overzealous attempts to reduce the hernia are unwarranted and potentially harmful to the tube and ovary. The risk that incarceration of the ovary in this setting will lead to strangulation is not known. Most pediatric surgeons recommend elective repair of the hernia within 24-48 hr. For any patient who presents with a prolonged history of incarceration, signs of peritoneal irritation, or small bowel obstruction, surgery and operative reduction and repair of the hernia should be urgently performed.

**Operative Management**

When the hernia cannot be reduced or signs of strangulation are present, immediate operation is indicated to prevent further damage to the contents of the hernia sac or testis. If there are signs of intestinal obstruction or strangulation, urgent, initial management includes nasogastric intubation, intravenous fluids, and administration of broad-spectrum antibiotics. When fluid and electrolyte imbalance has been corrected and the child’s condition is satisfactory, exploration is undertaken. The operation consists of opening of the inguinal canal, reduction of the contents of the hernia sac, separation of the hernia sac from the spermatic cord vessels and vas deferens in the inguinal canal, and high ligation of the hernia sac at the internal ring. Resection of nonviable structures within the hernia sac or of an infarcted testis may be indicated based on the experience and judgment of the surgeon. Although often the testis might appear ischemic, most testes recover after the incarceration is relieved and should not be removed.

The elective operative repair of a congenital indirect inguinal hernia is straightforward and consists of high ligation of the hernia sac (PV) at the level of the internal ring, thus preventing protrusion of abdominal contents into the inguinal canal. In boys, this requires careful separation of the sac from the spermatic cord structures and avoidance of injury to these vital structures. An associated hydrocele, present approximately 20% of the time, is released anteriorly to avoid injury to the spermatic cord structures located posteriorly. In girls, surgical repair is simpler because the hernia sac and round ligament can be ligated without concern for injury to the ovary and its blood supply, which generally remain within the abdomen. If the ovary and fallopian tube are within the sac and not reducible, the sac is ligated distal to these structures and the internal ring is closed after reducing the sac and its contents to the abdominal cavity.

**Laparoscopic Inguinal Hernia Repair**

Although the classic open inguinal hernia repair is most commonly performed, laparoscopic repair is increasingly used by pediatric surgeons experienced in the technique. Like the open technique, the laparoscopic technique is fundamentally a high ligation of the indirect inguinal hernia sac. In the open surgical technique, a small inguinal skin crease incision is employed, the inguinal canal is opened and careful identification and separation of the hernia sac from the vas deferens and the testicular blood supply is performed, followed by high ligation of the sac at the level of the internal ring (entrance point to the peritoneal cavity). In female infants, opening of the sac to visualize the ovary and fallopian tube may help avoid injury to these structures during suture ligation of the sac and also rule out testicular feminization syndrome. In laparoscopic inguinal hernia repair, the hernia sac, anterior to the vas deferens and the testicular blood vessels, is suture-ligated at the internal ring without inguinal exploration or handling of the spermatic cord structures. Proponents of the laparoscopic approach cite ease of examining the contralateral internal ring, decreased manipulation of the vas deferens and spermatic vessels, decreased operative time, and an ability to identify unsuspected direct or femoral hernias. In a prospective, randomized study, the laparoscopic approach was associated with decreased pain, parental perception of faster recovery, and parental perception of better wound cosmesis; however, complication and recurrence rates have been slightly higher for the laparoscopic approach and the approach has yet to gain wide acceptance. Laparoscopic procedures in infants should always be performed expeditiously and with low insufflations to pressure to avoid the risk of cardiorespiratory compromise. Postoperative pain in both techniques is managed with oral acetaminophen for 24-48 hr; older children may require a brief period of postoperative narcotics.

**Contralateral Inguinal Exploration**

Controversy exists regarding when to proceed with contralateral groin exploration in infants and children with a unilateral indirect inguinal hernia. The only purpose of contralateral exploration is to avoid the occurrence of a hernia on that side at a later date. The advantages of contralateral exploration include avoidance of parental anxiety and
possibly a second anesthesia, the cost of additional surgery, and the risk of contralateral incarceration. The disadvantages of exploration include potential injury to the spermatic cord vessels, vas deferens, and testis; increased operative and anesthesia time; and the fact that, in many infants, it is an unnecessary procedure. The relevant issues in the debate revolve around the frequency of occurrence of contralateral hernias after one-sided hernia repair and the relation of this to age, gender, and side of the clinically apparent hernia. Most large series noted a chance of developing a contralateral hernia following inguinal hernia repair as 30-40% in children younger than 2 yr of age, leading most pediatric surgeons to recommend routine contralateral exploration in this age group. Unfortunately, infants and young children have delicate spermatic cord structures and when boys were studied 8-20 yr after inguinal hernia repair, 5.8% of them had decreased testicular size on the side of the repair and 1% had testicular atrophy. In girls, because of the higher incidence of bilateral inguinal hernias and elimination of concern for injury to the spermatic cord or testis, routine contralateral exploration is recommended up to age 5 or 6 yr. Laparoscopy enables assessment of the contralateral side without risk of injury to the spermatic cord structures or testis. This procedure can be performed through an umbilical incision or by passing a 30-degree or 70-degree oblique scope through the open hernia sac just before ligation of the hernia sac on the involved side. If patency of the contralateral side is demonstrated, the surgeon can proceed with bilateral hernia repair, and if the contralateral side is properly obliterated, exploration and potential complications are avoided. The downside of this approach include the risks associated with laparoscopy, and that laparoscopy cannot differentiate between a patent PV and a true hernia (Figs. 346-2 and 346-3). Infants and children with risk factors for development of an inguinal hernia or with medical conditions that increase the risk of general anesthesia should be approached with a low threshold for routine contralateral exploration.

DIRECT INGUINAL HERNIA

Direct inguinal hernias are rare in children; approximately 0.5-1%. Direct hernias appear as groin masses that extend toward the femoral vessels with exertion or straining. The etiology is from a muscular defect or weakness in the floor of the inguinal canal medial to the epigastric vessels. Thus, direct inguinal hernias in children are generally considered an acquired defect. In one-third of cases, the patient has a history of a prior indirect hernia repair on the side of the direct hernia, which suggests a possible injury to the floor muscles of the inguinal canal at the time of the first herniorrhaphy. Patients with connective tissue disorders such as Ehlers-Danlos syndrome or Marfan syndrome and mucopolysaccharidosis such as Hunter-Hurler syndrome are at increased risk for the development of direct inguinal hernias either independently or after indirect inguinal hernia repair.

Operative repair of a direct inguinal hernia involves strengthening of the floor of the inguinal canal, and many standard techniques have been described, similar to repair techniques used in adults. The repair can be performed through a single limited incision and, therefore, laparoscopic repair does not offer significant advantage. Recurrence after repair, in contrast to that in adults, is extraordinarily rare. Because typically the area of muscular weakness is small and pediatric tissues have greater elasticity, primary repair is usually possible. Prosthetic material for direct hernia repair or other approaches, such as preperitoneal repair, are rarely required in the pediatric age group. The older child with a direct inguinal hernia and a connective tissue disorder may be the exception, and a laparoscopic approach and prosthetic material in such a case can be useful for repair.

FEMORAL HERNIA

Femoral hernias are also rare in children (<1% of groin hernias in children). They are more common in girls than boys, with a ratio of 2:1. They are extremely rare in infancy and occur typically in older children. Femoral hernias represent a protrusion through the femoral canal. The bulge of a femoral hernia is located below the inguinal ligament and typically projects toward the medial aspect of the proximal thigh. Femoral hernias are more often missed clinically than direct hernias on physical examination or at the time of indirect hernia repair. Repair of a femoral hernia involves closure of the defect at the femoral canal, generally suturing the inguinal ligament to the pectineal ligament/fascia.

COMPICATIONS

Complications after elective inguinal hernia repair are uncommon (=1.5%) but significantly higher in association with incarceration (=10%). The major risk of elective inguinal hernia repair in infants and children relates to the need for general anesthesia. Surgical complications can be related to technical factors (recurrence, iatrogenic cryptorchidism, inadvertent injury to the vas deferens or spermatic vessels), or to the underlying process, such as bowel ischemia, gonadal infarction, and testicular atrophy following incarceration.

Wound Infection

Wound infection occurs in <1% of elective inguinal hernia repairs in infants and children, but the incidence increases to 5-7% in association with incarceration and emergent repair. The patient typically develops fever and irritability 3-5 days after the surgery, and the wound demonstrates warmth, erythema, and fluctuance. Management consists of opening and draining the wound, a short course of antibiotics, and a
daily wound dressing. Most common organisms are Gram-positive (*Staphylococcus* and *Streptococcus* spp.), and consideration should be given to coverage of methicillin-resistant *Staphylococcus aureus*. The wound generally heals in 1-2 wk with low morbidity and a good cosmetic result.

**Recurrent Hernia**

The recurrence rate of inguinal hernias after elective inguinal hernia repairs is generally reported as 0.5-1.0%, with rates as high as 2% for premature infants. The rate of recurrence after emergency repair of an incarcerated hernia is much higher; reported as 3-8% in most large series. The true incidence of recurrence is most certainly even higher, given the problem of accurate long-term follow-up. In the group of patients who develop recurrent inguinal hernia, the recurrence occurs in 50% within 1 yr of the initial repair and in 75% by 2 yr. Recurrence of an indirect hernia is most likely the result of a technical problem in the original procedure, such as failure to identify the sac properly, failure to perform high ligation of the sac at the level of the internal ring, or a tear in the sac that leaves a strip of peritoneum along the cord structures. Recurrence as a direct hernia can result from injury to the inguinal floor (transversalis fascia) during the original procedure or failure to identify a direct hernia during the original exploration. Patients with connective tissue disorders (collagen deficiency) or conditions that cause increased intraabdominal pressure (ventriculo-peritoneal shunts, ascites, peritoneal catheter for dialysis) are at increased risk for recurrence.

**Iatrogenic Cryptorchidism**

Iatrogenic cryptorchidism describes malposition of the testis after inguinal hernia repair. This complication is usually related to disruption of the testicular attachment in the scrotum at the time of hernia repair or failure to recognize an undescended testis during the original procedure, allowing the testes to retract, typically to the region of the external ring. At the completion of inguinal hernia repair, the testis should be placed in a dependent intrascrotal position. If the testis will not remain in this position, proper fixation in the scrotum should be performed at the time of the hernia repair.

**Incarceration**

Incarceration of an inguinal hernia can result in injury to the intestines, the fallopian tube and ovary, or the ipsilateral testes. The incidence of incarceration of a congenital indirect inguinal hernia is reported as 6-18% throughout childhood and as high as 30% for infants younger than 3 mo of age. Intestinal injury requiring bowel resection is uncommon, occurring in only 1-2% of incarcerated hernias. In cases of incarceration in which the hernia is reduced nonoperatively, the likelihood of intestinal injury is low; however, these patients should be observed closely for 6-12 hr following reduction of the hernia persistent for signs and symptoms of intestinal obstruction, such as fever, vomiting, abdominal distention, or bloody stools.

The reported incidence of testicular infarction and subsequent testicular atrophy with incarceration is 4-12%, with higher rates among the irreducible cases requiring emergency operative reduction and repair. The testicular insult can be caused by compression of the gonadal vessels by the incarcerated hernia mass or as a result of damage incurred during operative repair. Young infants are at highest risk, with testicular infarction rates reported as high as 30% in infants younger than 2-3 mo of age. These problems underscore the need for prompt reduction of incarcerated hernias and early repair once the diagnosis is known to avoid repeat episodes of incarceration.

**Injury to the Vas Deferens and Male Fertility**

Similar to the gonadal vessels, the vas deferens can be injured as a consequence of compression from an incarcerated hernia or during operative repair. This injury is almost certainly underreported because it is unlikely to be recognized until adulthood and, even then, possibly only if the injury is bilateral. Although the vulnerability of the vas deferens has been documented in many studies, no good data exist as to the actual incidence of this problem. One review reported an incidence of injury to the vas deferens of 1.6% based on pathology demonstrating segments of the vas deferens in the hernia sac specimen; this may be overstated, because others have shown that small glandular inclusions found in the hernia sac can represent müllerian duct remnants and are of no clinical importance. The relationship between male fertility and previous inguinal hernia repair is also unknown. There appears to be an association between infertile males with testicular atrophy and abnormal sperm count and a previous hernia repair. A relationship has also been reported between infertile males with spermatic autoagglutinating antibodies and previous inguinal hernia repair. The proposed etiology is that operative injury to the vas deferens during inguinal hernia repair might result in obstruction of the vas with diversion of spermatozoa to the testicular lymphatics, and this breach of the blood–testis barrier produces an antigenic challenge, resulting in formation of spermatic autoagglutinating antibodies.

Bibliography
The human pancreas develops from the ventral and dorsal domains of
the primitive duodenal endoderm beginning at about the 5th wk of
 gestation (Fig. 347-1). The larger dorsal anlage, which develops into
the tail, body, and part of the head of the pancreas, grows directly
from the duodenum. The smaller ventral anlage develops as 1 or 2 buds
from the primitive liver and eventually forms the major portion of the
head of the pancreas. At about the 17th wk of gestation, the dorsal and
ventral anlagen fuse as the buds develop and the gut rotates. The
ventral duct forms the proximal portion of the major pancreatic duct
of Wirsung, which opens into the ampulla of Vater. The dorsal duct
forms the distal portion of the duct of Wirsung and the accessory
duct of Santorini, which empties independently in approximately 5%
of people. Variations in fusion might account for pancreatic develop-
mental anomalies. Pancreatic agenesis has been associated with a base
pair deletion in the ipf1 HOX gene, PDX1, and possibly in the PTF1A
and FS123TER genes. Other genes involved in pancreatic organogen-
esis include the IHH, SHH or sonic hedgehog gene, SMAD2, and
transforming growth factor-1β genes.

The pancreas lies transversely in the upper abdomen between the
duodenum and the spleen in the retroperitoneum (Fig. 347-2). The
head, which rests on the vena cava and renal vein, is adherent to
the C loop of the duodenum and surrounds the distal common bile
duct. The tail of the pancreas reaches to the left splenic hilum and
passes above the left kidney. The lesser sac separates the tail of the
pancreas from the stomach.

By the 13th wk of gestation, exocrine and endocrine cells can be
identified. Primitive acini containing immature zymogen granules are
found by the 16th wk. Mature zymogen granules containing amylase,
An annullar pancreas results from incomplete rotation of the left (ventral) pancreatic anlage, which may be a result of recessive mutations in the IHH or SHH genes. Patients usually present in infancy with symptoms of complete or partial bowel obstruction or in the 4th or 5th decade. There is often a history of maternal polyhydramnios. Other congenital anomalies, such as Down syndrome, tracheoesophageal fistula, intestinal atresia, imperforate anus, malrotation and cardiorenal abnormalities, and pancreatitis, may be associated with annular pancreas. Some children present with chronic vomiting, pancreatitis, or biliary colic. The treatment of choice is duodenojunostomy. Division of the pancreatic ring is not attempted, because a duodenal diaphragm or duodenal stenosis often accompanies annular pancreas.

Ectopic pancreatic rests in the stomach or small intestine occur in approximately 3% of the population. Most cases (70%) are found in the upper intestinal tract. Recognized on barium contrast studies by their typical umbilicated appearance, they are rarely of clinical importance. On endoscopy, they are irregular, yellow nodules 2-4 mm in diameter. A pancreatic rest may rarely be the lead point of an intussusception, produce hemorrhage, or cause bowel obstruction.

Pancreas divisum, which occurs in 5-15% of the population, is the most common pancreatic developmental anomaly. As the result of failure of the dorsal and ventral pancreatic anlagen to fuse, the tail, body, and part of the head of the pancreas drain through the small accessory duct of Santorini rather than the main duct of Wirsung. Some investigators believe that this anomaly may be associated with recurrent pancreatitis when there is relative obstruction of the outflow of the ventral pancreas. Diagnosis is made by endoscopic retrograde cholangiopancreatography or by magnetic resonance cholangiopancreatography. It was recently shown that pancreatitis in patients with pancreas divisum is associated with mutations in the CFTR gene. Sphincterotomy is no longer recommended in these patients unless other anomalies are present.

Choleodochal cysts are dilations of the biliary tract and usually cause biliary tract symptoms, such as jaundice, pain, and fever. On occasion, the presentation may be pancreatitis. The diagnosis is usually made with ultrasonography, CT or biliary scanning, or magnetic resonance cholangiopancreatography. Similarly, a choledochocele, an intraduodenal choledochal cyst may manifest with pancreatitis. The diagnosis can be difficult and require magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, or endoscopic ultrasound.

A number of rare conditions, such as Ivemark and Johanson-Blizzard syndromes include pancreatic dysgenesis or dysfunction among their features. Many of these syndromes include renal and hepatic dysgenesis along with the pancreatic anomalies.

The acinus is the functional unit of the exocrine pancreas. Acinar cells are arrayed in a semicircle around a lumen. Ducts that drain the acini are lined by centroacinar and ductular cells. This arrangement allows the secretions of the various cell types to mix.

The acinar cell synthesizes, stores, and secretes more than 20 enzymes, which are stored in zymogen granules, some in inactive forms. The relative concentration of the various enzymes in pancreatic juice is affected and perhaps controlled by the diet, probably by regulating the synthesis of specific messenger RNA. The main enzymes involved in digestion include amylase, which splits starch into maltose, isomaltose, maltotriose; dextrins; and trypsin and chymotrypsin, endopeptidases secreted by the pancreas as inactive proenzymes. Trypsinogen is activated in the gut lumen by enterokinase, a brush-border enzyme. Trypsin can then activate trypsinogen, chymotrypsinogen, and procarboxylypeptidase into their respective active forms. Pancreatic lipase requires colipase, a coenzyme also found in pancreatic fluid, for activity. Lipase liberates fatty acids from the 1 and 3 positions of triglycerides, leaving a monoglyceride.

The stimuli for exocrine pancreatic secretion are neural and hormonal. Acetylcholine mediates the cephalic phase; cholecystokinin (CCK) mediates the intestinal phase. CCK is released from the duodenal mucosa by luminal amino acids and fatty acids. Feedback regulation of pancreatic secretion is mediated by pancreatic proteases in the duodenum. Secretion of CCK is inhibited by the digestion of a trypsin-sensitive, CCK-releasing peptide released in the lumen of the small intestine or by a monitor peptide released in pancreatic fluid.

Centroacinar and duct cells secrete water and bicarbonate. Bicarbonate secretion is under feedback control and is regulated by duodenal intraluminal pH. The stimulus for bicarbonate production is secretin in concert with CCK. Secretin cells are abundant in the duodenum.

Although normal pancreatic function is required for digestion, malabsorption occurs only after considerable reduction in pancreatic function; lipase and colipase secretion must be decreased by 90-98% before fat malabsorption occurs.

Although amylase and lipase are present in the pancreas early in gestation, secretion of both amylase and lipase is low in the infant. Adult levels of these enzymes are not reached in the duodenum until late in the 1st yr of life. Digestion of the starch found in many infant formulas depends in part on the low levels of salivary amylase that reach the duodenum. This explains the diarrhea that may be seen in infants who are fed formulas high in glucose polymers or starch. Neonatal secretion of trypsinogen and chymotrypsinogen is at approximately 70% of the level found in the 1 yr old infant. The low levels of amylase and lipase in duodenal contents of infants may be partially compensated by salivary amylase and lingual lipase. This explains the relative starch and fat intolerance of premature infants.

Bibliography

The standard screening test for pancreatic insufficiency, has a sensitivity and specificity > 90%. A fecal elastase > 100 µg/g of stool has a 99% predictive value in ruling out pancreatic insufficiency based on an abnormal 72 hr fecal fat. Falsely abnormal results can occur in many enteropathies, such as celiac disease, and when the stool is very loose. The activity of other pancreatic enzymes in stool is now rarely measured.

**DIRECT TESTING**

Classically, a triple-lumen tube was used to isolate the pancreatic secretions in the duodenum. Measurement of bicarbonate concentration and enzyme activity (trypsin, chymotrypsin, lipase, and amylase) is performed on the aspirated secretions. Because this test is cumbersome and time consuming it is infrequently used except in the research setting. Although the most commonly used direct test is collection of pancreatic juice at endoscopy after stimulation with secretin and/or cholecystokinin there is controversy over this approach.

A 72 hr stool collection for quantitative analysis of fat content is the gold standard for the diagnosis of malabsorption. The collection is usually performed at home, and the parent is asked to keep a careful dietary record, from which fat intake is calculated. A preweighed, sealable plastic container is used, which the parent keeps in the freezer. Freezing helps to preserve the specimen and reduce odor. Infants are dressed in disposable diapers with the plastic side facing the skin so that the complete sample can be transferred to the container. Normal fat absorption is >93% of intake. The presence of fat malabsorption does not differentiate between pancreatic dysfunction and enteropathies, such as celiac disease. Qualitative examination of the stool for microscopic fat globules can give false-positive and false-negative results.

Pancreatic function can also be measured by a breath test using $^{13}$C-triolein as the substrate. This test has not gained widespread acceptance because it is relatively insensitive in detecting mild cases of pancreatic insufficiency, and detection of $^{13}$CO$_2$ requires a mass spectrophotometer that is not generally available.

Disorders of the Exocrine Pancreas

Steven L. Werlin and Michael Wilschanski

DISORDERS ASSOCIATED WITH PANCREATIC INSUFFICIENCY

Other than cystic fibrosis, conditions that cause pancreatic insufficiency are very rare in children. They include Shwachman-Diamond syndrome, Johanson-Blizzard syndrome, isolated enzyme deficiencies, enterokinase deficiency (see Chapter 338), chronic pancreatitis, and protein-calorie malnutrition (see Chapters 46 and 338).

CYSTIC FIBROSIS

(See Chapter 403.)

Cystic fibrosis (CF) is the most common lethal genetic disease in white children. By the end of the 1st yr of life, 85-90% of children with CF have pancreatic insufficiency, which, if untreated, will lead to malnutrition. Treatment of the associated pancreatic insufficiency leads to improvement in absorption, better growth, and more normal stools.
Pancreatic function can be monitored in children with CF with serial measurements of fecal elastase. Ten percent to 15% of CF patients are pancreatic sufficient and their presentation tends to be later in life, including recurrent pancreatitis, male infertility, and chronic bronchiectasis. CF is part of the newborn screen in every state in the United States and in most countries in the Western world.

**SHWACHMAN-DIAMOND SYNDROME**

(See Chapter 131.)

Shwachman-Diamond syndrome (SDS) is an autosomal recessive syndrome (1 per 20,000 births) caused by a mutation of the Shwachman-Bodian-Diamond (SBDS) gene on chromosome 7, which causes ribosomal dysfunction in 90-95% of patients. Signs and symptoms of SDS include pancreatic insufficiency; neutropenia, which may be cyclic, neutrophil chemotaxis defects, metaphyseal dysostosis, failure to thrive, and short stature. Some patients with SDS have liver or kidney involvement, dental disease, or learning difficulty. SDS is a common cause of congenital neutropenia.

Patients typically present in infancy with poor growth and steatorrhea. These children can be readily differentiated from those with CF by their normal sweat chloride levels, lack of mutations in the CF gene, characteristic metaphyseal lesions, and fatty pancreas characterized by a hypodense appearance on CT and MRI scans.

Despite adequate pancreatic replacement therapy and correction of malabsorption, poor growth commonly continues. Pancreatic insufficiency is often transient, and steatorrhea frequently spontaneously improves with age. Recurrent pyogenic infections (otitis media, pneumonia, osteomyelitis, dermatitis, sepsis) are frequent and are a common cause of death. Thrombocytopenia is found in 70% of patients and anemia in 50%. Development of a myelodysplastic syndrome can occur, with transformation to acute myeloid leukemia in 24%. The pancreatic acini are replaced by fat with little fibrosis. Islet cells and ducts are normal. Bone marrow transplant is the treatment of choice in patients who develop acute myeloid leukemia.

**PEARSON SYNDROME**

Pearson syndrome is caused by a mitochondrial DNA mutation affecting oxidative phosphorylation that manifests in infants with severe macrocytic anemia and variable thrombocytopenia. The bone marrow demonstrates vacuoles in erythroid and myeloid precursors as well as ringed sideroblasts. In addition to its role in severe bone marrow failure, pancreatic insufficiency contributes to growth failure. Mitochondrial DNA mutations are transmitted through maternal inheritance to both sexes or are sporadic.

**JOHANSON-BLIZZARD SYNDROME**

The features of the Johanson-Blizzard syndrome include exocrine pancreatic deficiency, aplasia or hypoplasia of the alae nasi, congenital deafness, hypothyroidism, developmental delay, short stature, ectodermal scalp defects, absence of permanent teeth, urogenital malformations, and imperforate anus. This syndrome is caused by a mutation in the UBRI gene found on chromosome 15. The UBR1 protein acts as a ubiquitin ligase.

**ISOLATED ENZYME DEFICIENCIES**

Isolated deficiencies of trypsinogen, enterokinase, lipase, and colipase have been reported. Although enterokinase is a brush-border enzyme, deficiency causes pancreatic insufficiency because enterokinase is required to activate trypsinogen to trypsin in the duodenum. Deficiencies of trypsinogen or enterokinase manifest with failure to thrive, hypoproteinemina, and edema. Isolated amylase deficiency is typically developmental and resolves by age 2-3 yr.

**OTHER SYNDROMES ASSOCIATED WITH PANCREATIC INSUFFICIENCY**

Pancreatic agenesis, congenital pancreatic hypoplasia, and congenital rubella are rare causes of pancreatic insufficiency. Pancreatic insufficiency has also been reported in duodenal atresia and stenosis and may also be seen in an infant with familial or nonfamilial hyperinsulinemic hypoglycemia, who requires 95-100% pancreatectomy to control hypoglycemia. Pancreatic insufficiency, which may be found in children with celiac disease and undernutrition, recovers with nutritional rehabilitation.

Chapter 350

Treatment of Pancreatic Insufficiency

Steven L. Werlin and Michael Wilschanski

The most important therapy of pancreatic insufficiency is pancreatic enzyme replacement therapy (PERT). The enzymes are enterically coated to protect the enzymes from degradation by gastric acid and from autodigestion in the small intestine. It is common for patients to change from one product to another using a 1:1 lipase ratio and then titrating for maximum efficacy.

The North American Cystic Fibrosis Foundation has published dosing guidelines based on age and fat ingestion (Table 350-1). Because these products contain excess protease compared with lipase, the dosage is estimated from the lipase requirement. The final dosage of PERT for children is often established by trial and error. An adequate dose is one that is followed by resumption of normal growth and the return of the stools to normal fat content, which, when desired, can be verified by a 72-hr fecal fat collection and normalization of stool consistency color. Because there is no elastase in enzyme preparations, fecal elastase can not be used to monitor appropriateness of PERT dosage. Enzyme replacement should be divided and given at the beginning of and during the meal. Enzymes should not be chewed, crushed, or dissolved in food, which would allow gastric acid to penetrate the enteric coating and destroy the enzymes. Enzymes must also be given with snacks, which contain fat. Increasing enzyme supplements beyond the recommended dose does not improve absorption, might retard growth, and can cause fibrosing colonopathy (see below).

A major issue has been the ingestion of enzymes by infants. The importance of correct enzyme ingestion in infants and children is obvious but there may be difficulty in feeding the infant microspheres, however small they may be. Enterically coated microspheres can be

</table>

mixed with apple sauce for oral use or crushed for use in tube feeding. Patients treated with this approach achieve growth and weight gain, proving their efficacy.

Treatment of exocrine pancreatic insufficiency by oral enzyme replacement usually corrects protein malabsorption, but steatorrhea is difficult to completely correct. Factors contributing to fat malabsorption include inadequate dosage, incorrect timing of doses in relation to food consumption or gastric emptying, lipase inactivation by gastric acid, and the observation that chymotrypsin in the enzyme preparation digests and thus inactivates lipase.

When adequate fat absorption is not achieved, gastric acid neutralization with an H₂-receptor antagonist or, more commonly, a proton pump inhibitor, decreases enzyme inactivation by gastric acid and thus improves delivery of lipase into the intestine. Enteric coating also protects lipase from acid inactivation.

Untoward effects secondary to PERT include allergic reactions, increased uric acid levels, and kidney stones. Fibrosing colonopathy, consisting of colonic fibrosis and strictures, can occur 7-12 mo after overdose of PERT.

Fat-soluble vitamin supplements are required by pancreatic insufficiency patients because of the ongoing mild to moderate fat malabsorption that occurs despite PERT.

*Bibliography is available at Expert Consult.*
Bibliography
Acute pancreatitis, the most common pancreatic disorder in children, is increasing in incidence and at least 30–50 cases are now seen in major pediatric centers per year. In children, blunt abdominal injuries, multisystem disease such as the hemolytic uremic syndrome and inflammatory bowel disease, biliary stones or microlithiasis (sludging), and drug toxicity are the most common etiologies. Although many drugs and toxins can induce acute pancreatitis in susceptible persons, in children, valproic acid, l-asparaginase, 6-mercaptopurine, and azathioprine are the most common causes of drug-induced pancreatitis. Other cases follow organ transplantation or are caused by infections, metabolic disorders, or mutations in susceptibility genes (see Chapter 351.2). Fewer than 5% of cases are idiopathic (Table 351-1).

After an initial insult, such as ductal disruption or obstruction, there is premature activation of trypsinogen to trypsin within the acinar cell. Trypsin then activates other pancreatic proenzymes, leading to autodigestion, further enzyme activation, and release of proteolytic enzymes. Lysosomal hydrolases colocalize with pancreatic proenzymes within the acinar cell. Pancreatitis (similar in concept to cholestasis) with continued synthesis of enzymes occurs. Lecithin is unstable and can be activated by minute quantities of trypsin. After the insult, cytokines and other proinflammatory mediators are released.

The healthy pancreas is protected from autodigestion by pancreatic proteases that are synthesized as inactive proenzymes; digestive enzymes that are segregated into secretory granules at pH 6.2 by low calcium concentration, which minimizes trypsin activity; the presence of protease inhibitors both in the cytoplasm and zymogen granules; and enzymes that are secreted directly into the ducts.

Histopathologically, interstitial edema appears early. Later, as the episode of pancreatitis progresses, localized and confluent necrosis, blood vessel disruption leading to hemorrhage, and an inflammatory response in the peritoneum can develop.

Criteria for the diagnosis of pancreatitis in children are defined as 2 of 3 of the following: abdominal pain; serum amylase and/or lipase activity at least 3 times greater than the upper limit of normal; and imaging findings characteristic of, or compatible with, acute pancreatitis.

CLINICAL MANIFESTATIONS

Mild Acute Pancreatitis

The patient with acute pancreatitis has severe abdominal pain, persistent vomiting, and possibly fever. The pain is epigastric or in either upper quadrant, steady, often resulting in the child’s assuming an anatomic position with hips and knees flexed, sitting upright, or lying on the side. The child is very uncomfortable and irritable and appears acutely ill. The abdomen may be distended and tender and a mass may be palpable. The pain can increase in intensity for 24–48 hr, during which time vomiting may increase and the patient can require hospitalization for dehydration and might need fluid and electrolyte therapy. The prognosis for complete recovery in the acute uncomplicated case is excellent.

Severe Acute Pancreatitis

Severe acute pancreatitis is rare in children. In this life-threatening condition, the patient is acutely ill with severe nausea, vomiting, and abdominal pain. Shock, high fever, jaundice, ascites, hypocalcemia, and pleural effusions can occur. A bluish discoloration may be seen around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign). The pancreas is necrotic and can be transformed into an inflammatory hemorrhagic mass. The mortality rate, which is approximately 20%, is related to the systemic inflammatory response syndrome with multiple organ dysfunction, shock, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, massive gastrointestinal bleeding, and systemic or intraabdominal infection. The percentage of necrosis seen on CT scan and failure of pancreatic tissue to enhance on CT scan (suggesting necrosis) predicts the severity of the disease.

DIAGNOSIS

Acute pancreatitis is usually diagnosed by measurement of serum lipase and amylase activities. Serum lipase is now considered the gold standard test for acute inflammatory pancreatic disease and should be determined when pancreatitis is suspected. The serum lipase rises by 4–8 hr, peaks at 24–48 hr, and remains elevated 8–14 days longer than serum amylase. Serum lipase can be elevated in nonpancreatic diseases. The serum amylase level is typically elevated for up to 4 days. A variety of other conditions can also cause hyperamylasemia without pancreatitis (Table 351-2). Elevation of salivary amylase can mislead the clinician to diagnose pancreatitis in a child with abdominal pain. The laboratory can separate amylase isoenzymes into pancreatic and salivary fractions. Initially, serum amylase levels are normal in 10–15% of patients.

Other laboratory abnormalities that may be present in acute pancreatitis include hyperamylasemia, hypercalcinemia, hyperglycemia, glucosuria, hypocalcemia, elevated γ-glutamyl transpeptidase, and hyperbilirubinemia.

X-ray of the chest and abdomen might demonstrate nonspecific findings. The chest x-ray might demonstrate atelectasis, basilar infiltrates, elevation of the hemidiaphragm, left- (rarely right-) sided pleural effusions, pericardial effusion, and pulmonary edema. Abdominal x-rays might demonstrate a sentinel loop, dilation of the transverse colon (cutoff sign), ileus, pancreatic calcification (if recurrent), blurring of the left psoas margin, a pseudocyst, diffuse abdominal haziness (ascites), and peripancreatic extraluminal gas bubbles.

CT scanning has a major role in the diagnosis and follow-up of children with pancreatitis. Findings can include pancreatic enlargement, a hypoechoic, sonolucent edematous pancreas, pancreatic masses, fluid collections, and abscesses (Fig. 351-1); 20% or more of children with acute pancreatitis initially have normal imaging studies. In adults, CT findings are the basis of a widely accepted prognostic system. Ultrasonography is more sensitive than CT scanning for the diagnosis of biliary stones. Magnetic resonance cholangiopancreatography and endoscopic retrograde cholangiopancreatography are essential in the investigation of recurrent pancreatitis, nonresolving pancreatitis, and disease associated with gallbladder pathology. Endoscopic ultrasonography also helps visualize the pancreaticobiliary system.

TREATMENT
The aims of medical management are to relieve pain and restore metabolic homeostasis. Analgesia should be given in adequate doses. Fluid, electrolyte, and mineral balance should be restored and maintained. Nasogastric suction is useful in patients who are vomiting. While vomiting, the patient should be maintained with nothing by mouth. Recovery is usually complete within 4-5 days. Refeeding can commence when vomiting has resolved. Early refeeding by nasogastric tube or on demand decreases the complication rate and length of stay.

In severe pancreatitis, antibiotics are used to treat infected necrosis but prophylactic antibiotics are not recommended. Gastric acid is suppressed. Endoscopic therapy can be of benefit when pancreatitis is caused by anatomic abnormalities, such as strictures or stones. Enteral
Pancreatitis

is rarely required but may include drainage of necrotic material or abscesses.

PROGNOSIS

Children with uncomplicated acute pancreatitis do well and recover within 4-5 days. When pancreatitis is associated with trauma or systemic disease, the prognosis is typically related to the associated medical conditions.

Bibliography is available at Expert Consult.

351.2 Chronic Pancreatitis

Steven L. Werlin and Michael Wilschanski

Chronic pancreatitis in children is often caused by genetic mutations or by congenital anomalies of the pancreatic or biliary ductal system. Mutations in the PRSS1 gene (cationic trypsinogen) located on the long arm of chromosome 7, in SPINK 1 gene (pancreatic trypsin inhibitor) located on chromosome 5, in the cystic fibrosis gene (CFTR), and in the chymotrypsin C gene (CTRC) may all lead to chronic pancreatitis (see Table 351-1).

Cationic trypsinogen has a trypsin-sensitive cleavage site. Loss of this cleavage site in the abnormal protein permits uncontrolled activation of trypsinogen to trypsin, which leads to autodigestion of the pancreas. Mutations in PRSS1 act in an autosomal dominant fashion with incomplete penetrance and variable expressivity. Symptoms often begin in the 1st decade but are usually mild at the onset. Although spontaneous recovery from each attack occurs in 4-7 days, episodes become progressively severe. Clinically, hereditary pancreatitis may be diagnosed by the presence of the disease in successive generations of

Figure 351-1 CT and MRI appearance of pancreatitis. **A,** Mild acute pancreatitis. Arterial phase spiral CT. Diffuse enlargement of pancreas without fluid accumulation. **B,** Severe acute pancreatitis. Lack of enhancement of the pancreatic parenchyma due to the necrosis of the entire pancreatic gland. **C,** Pancreatic pseudocyst. A round fluid collection with thin capsule is seen within the lesser sac. **D,** Acute severe pancreatitis and peripancreatic abscess formation. Peripancreatic abscess formation is observed within the peripancreatic and the left anterior pararenal space. **E,** Pancreatic necrosis. A well-defined fluid attenuation collection in the pancreatic bed (white arrows) seen on contrast-enhanced CT imaging. **F,** The same collection is more complex appearing on the corresponding T2-weighted MR image. The internal debris and necrotic tissue are better appreciated because of the superior soft-tissue contrast of MRI (black arrows). pancreatitis. Irreversible pancreatic insufficiency followed by diabetes mellitus in childhood or early adulthood, manifesting with abdominal pain and pancreatic calcification in the head of the pancreas. Both types respond to steroids. There have been only a few case reports of this condition in children.

The pancreas is hypodense on CT. The pathogenesis is unknown. Type 1 is a systemic disease and is associated with high serum immunoglobulin levels, which later calcify. This condition is associated with mutations in the SPINK gene in 50% of cases.

A thorough diagnostic evaluation of every child with more than 1 episode of pancreatitis is indicated. Serum lipid, calcium, and phosphorus levels are determined. Stools are evaluated for ascaris, and a sweat test is performed. Plain abdominal films are evaluated for the presence of pancreatic calcifications. Abdominal ultrasound or CT scanning is performed to detect the presence of a pseudocyst (Figs. 351-3 and 351-4). The biliary tract is evaluated for the presence of stones. After genetic counseling, evaluation of PRSS1, SPINK1, CFTR, and CRTC genotypes can be measured.

Magnetic resonance cholangiopancreatography and endoscopic retrograde cholangiopancreatography are techniques that can be used to define the anatomy of the gland and are mandatory if surgery is considered. Magnetic resonance cholangiopancreatography is the test of choice when endotherapy is not being considered and should be performed as part of the evaluation of any child with idiopathic, nonresolving, or recurrent pancreatitis and in patients with a pseudocyst before drainage. In these cases a previously undiagnosed anatomic defect that may be amenable to endoscopic or surgical therapy may be detected. Endoscopic treatments include sphincterotomy, stone
extraction, drainage on pseudocysts, and insertion of pancreatic or biliary endoprosthetic stents. These treatments allow successful non-surgical management of conditions previously requiring surgical intervention. In patients with intractable pain total pancreatectomy and islet cell transfusion is performed in specialized centers.

Pseudocyst of the Pancreas

Steven L. Werlin and Michael Wilschanski

Pancreatic pseudocyst formation is an uncommon sequela to acute or chronic pancreatitis. Pseudocysts are sacs delineated by a fibrous wall in the lesser peritoneal sac. They can enlarge or extend in almost any direction, thus producing a wide variety of symptoms (see Fig. 351-1C).
Bibliography

Pancreatic tumors can be of either endocrine or nonendocrine origin. Tumors of endocrine origin include insulinomas and gastrinomas. These and other functioning tumors occur in the autosomal dominantly inherited multiple endocrine neoplasia type 1 (MEN-1). Hypoglycemia accompanied by higher-than-expected insulin levels or refractory gastric ulcers (Zollinger-Ellison syndrome) indicate the possibility of a pancreatic tumor (see Chapter 345). Most gastrinomas arise outside of the pancreas. The treatment of choice is surgical removal. If the primary tumor cannot be found, or if it has metastasized, cure might not be possible. Treatment with a high dose of a proton pump inhibitor to inhibit gastric acid secretion is then indicated.

The watery diarrhea–hypokalemia–acidosis syndrome is usually produced by the secretion of vasoactive intestinal peptide by a non–α-cell tumor (VIPoma) (see Table 341-7). Vasoactive intestinal peptide levels are often, but not always, increased in the serum. Treatment is surgical removal of the tumor. When this is not possible, symptoms may be controlled by the use of octreotide acetate (cyclic somatostatin, Sandostatin), a synthetic analog of somatostatin. Pancreatic tumors secreting a variety of hormones, including glucagon, somatostatin, and pancreatic polypeptide have also been described. The treatment is surgical resection when possible.

Pancreatoblastomas, pancreatic adenocarcinomas, cystadenomas, and rhabdomyosarcomas are rarely encountered. Pancreatoblastoma, a malignant embryonal tumor that secretes α-fetoprotein and can contain both endocrine and exocrine elements, is the most common pancreatic neoplasm in young children. Presurgical chemotherapy

Pancreatic Tumors

Steven L. Werlin and Michael Wilschanski
should be considered for lesions not primarily resectable. Resection can be curative; adjuvant chemotherapy has been used but its effectiveness is not established.

Carcinoma of the exocrine pancreas is a major problem in adults, accounting for 2% of diagnoses and 5% of deaths from cancer. It is very rare in childhood. No definite causes are known. Several genetic syndromes including mutations in the *PRSS1* and *MEN-1* genes lead to an increased incidence of pancreatic cancer in adult life. The Frantz tumor is a papillary cystic tumor usually found in girls and young women. Typical presenting symptoms are abdominal pain, mass, or jaundice. The treatment of choice is total surgical removal.

Insulinomas and persistent hyperinsulinemic hypoglycemia of infancy produce symptomatic hypoglycemia caused by mutations in a variety of genes, most commonly *GUUD1* and *KATP*. Massive subtotal or total pancreatectomy is the treatment of choice when medical treatment fails (see Chapter 86). These children might then develop pancreatic insufficiency and diabetes as a complication of surgery.

Pancreatic lesions in von Hippel-Lindau disease are usually benign and cystic. Cystadenomas, familial adenocarcinomas, and islet cell tumors are less common. Metastases have been reported, but adjuvant therapy after surgical excision cannot yet be recommended. The diagnosis is suggested by CT scanning.

Prognosis is good for completely resected endocrine tumors but very poor for carcinomas, even with extensive surgery. Children who survive partial or complete pancreatectomy may have decreased pancreatic exocrine and endocrine reserve.

Bibliography
During the early embryonic process of gastrulation, the 3 embryonic germ layers (endoderm, mesoderm, ectoderm) are formed. The liver and biliary system arises from cells of the ventral foregut endoderm; their development can be divided into 3 distinct processes (Fig. 354-1). First, through unknown mechanisms, the ventral foregut endoderm acquires competence to receive signals arising from the cardiac mesoderm. These mesodermal signals, in the form of various fibroblast growth factors and bone morphogenetic proteins, lead to specification of cells that have the potential to form the liver and activate liver-specific genes. During this period of hepatic fate decision, “pioneer” transcription factors, including Foxa and Gata4, bind to specific binding sites in compacted chromatin, open the local chromatin structure, and mark genes as competent. But these will only be expressed if they are correctly induced by additional transcription factors. Newly specified cells then delaminate from the ventral foregut endoderm and migrate in a cranial ventral direction into the septum transversum in the 4th wk of human gestation to initiate liver morphogenesis.

The growth and development of the newly budded liver require interactions with endothelial cells. Certain proteins are important for liver development in animal models (Table 354-1). In addition to these proteins, microRNAs, which consist of small noncoding, single-stranded RNAs, have a functional role in the regulation of gene expression and hepatobiliary development in zebrafish and mouse models. Within the ventral mesentery, proliferation of migrating cells form anastomosing hepatic cords, with the network of primitive liver cells, sinusoids, and septal mesenchyme establishing the basic architectural pattern of liver lobule (Fig. 354-2). The solid cranial portion of the hepatic diverticulum (pars hepatis) eventually forms the hepatic parenchyma and the intrahepatic bile ducts. The hepatic lobules are identifiable in the 6th wk of human gestation. The bile canalicular structures, including microvilli and junctional complexes, are specialized loci of the liver cell membrane; these appear very early in gestation, and large canaliculi bounded by several hepatocytes are seen by 6-7 wk.

Hepatocytes and bile duct cells (cholangiocytes) originate from hepatoblasts as common precursors. Notch signaling, which is impaired in Alagille syndrome, promotes hepatoblast differentiation into biliary epithelium, whereas hepatocyte growth factor antagonizes differentiation. The development of the intrahepatic bile ducts is determined by the development and branching pattern of the portal vein. Around the 8th wk of gestation, starting at the hilum of the liver, primitive hepatoblasts adjacent to the mesenchyme around the portal vein branches form a cylindrical sleeve, termed the ductal plate. From 12 wk of gestation onward, a “remodeling” of the ductal plate occurs, with some segments of the ductal plate undergoing tubular dilation and excess ductal plate cells gradually disappearing. The ramification of the biliary tree continues throughout human fetal life and at the time of birth the most peripheral branches of the portal veins are still surrounded by ductal plates; these require 4 more weeks to develop into definitive portal ducts. Lack of remodeling of the ductal plate results in persistence of primitive ductal plate configurations, an abnormality called ductal plate malformation. This histopathologic lesion has been

observed in liver biopsies of a variety of liver conditions, including congenital hepatic fibrosis, Caroli disease, and biliary atresia.

The caudal part (pars cystica) of the hepatic diverticulum becomes the gallbladder, cystic duct, and common bile duct. The distal portions of the right and left hepatic ducts develop from the extrahepatic ducts, whereas the proximal portions develop from the first intrahepatic ductal plates. The extrahepatic bile ducts and the developing intrahepatic biliary tree maintain luminal continuity and patency from the beginning of organogenesis (see Fig. 354-2C).

Fetal hepatic blood flow is derived from the hepatic artery and from the portal and umbilical veins, which form the portal sinus. The portal venous inflow is directed mainly to the right lobe of the liver and umbilical flow primarily to the left. The ductus venosus shunts blood from the portal and umbilical veins to the hepatic vein, bypassing the sinusoidal network. After birth, the ductus venosus becomes obliterated when oral feedings are initiated. The fetal oxygen saturation is lower in portal than in umbilical venous blood; accordingly, the right hepatic lobe has lower oxygenation and greater hematopoietic activity than the left hepatic lobe.

The transport and metabolic activities of the liver are facilitated by the structural arrangement of liver cell cords, which are formed by rows of hepatocytes, separated by sinusoids that converge toward the tributaries of the hepatic vein (the central vein) located in the center of the lobule (see Fig. 354-2D). This establishes the pathways and patterns of flow for substances to and from the liver. In addition to arterial input from the systemic circulation, the liver also receives venous input from the gastrointestinal tract via the portal system. The products of the hepatobiliary system are released by 2 different paths: through the hepatic vein and through the biliary system back into the intestine. Plasma proteins and other plasma components are secreted by the liver. Absorbed and circulating nutrients arrive through the portal vein or the hepatic artery and pass through the sinusoids and past the hepatocytes to the systemic circulation at the central vein. Biliary components are transported via the series of enlarging channels from the bile canaliculi through the bile ductule to the common bile duct.

Bile secretion is first noted at the 12th wk of human gestation. The major components of bile vary with stage of development. Near term, cholesterol and phospholipid content is relatively low. Low concentrations of bile acids, the absence of bacterially derived (secondary) bile acids, and the presence of unusual bile acids reflect low rates of bile flow and immature bile acid synthetic pathways.

The liver reaches a peak relative size of approximately 10% of the fetal weight at the 9th wk. Early in development, the liver is a primary site of hematopoiesis. In the 7th wk, hematopoietic cells outnumber functioning hepatocytes in the hepatic anlage. These early hepatocytes are smaller than at maturity (~20 µm vs 30-35 µm) and contain less glycogen. Near term, the hepatocyte mass expands to dominate the organ, as cell size and glycogen content increase. Hematopoiesis is virtually absent by the 2nd postnatal month in full-term infants. As the density of hepatocytes increases with gestational age, the relative volume of the sinusoidal network decreases. The liver constitutes 5% of body weight at birth but only 2% in an adult.

Several metabolic processes are immature in a healthy newborn infant, owing in part to the fetal patterns of activity of various enzymatic processes. Many fetal hepatic functions are carried out by the maternal liver, which provides nutrients and serves as a route of elimination of metabolic end products and toxins. Fetal liver metabolism is devoted primarily to the production of proteins required for growth.
Hepatocytes exhibit various ultrastructural features that reflect their biologic functions (Fig. 354-3). Hepatocytes, like other epithelial cells, are polarized, meaning that their structure and function are directionally oriented. One result of this polarity is that various regions of the hepatocyte plasma membrane exhibit specialized functions. Bidirectional transport occurs at the sinusoidal surface, where materials reaching the liver via the portal system enter and compounds secreted by the liver leave the hepatocyte. Canaliculai membranes of adjacent hepatocytes form bile canaliculi, which are bounded by tight junctions, preventing transfer of secreted compounds back into the sinusoid. Within hepatocytes, metabolic and synthetic activities are contained within a number of different cell organelles. The oxidation and metabolism of heterogeneous classes of substrates, fatty acid oxidation, key processes in gluconeogenesis, and the storage and release of energy occur in the abundant mitochondria.

The endoplasmic reticulum, a continuous network of rough- and smooth-surfaced tubules and cisternae, is the site of various processes, including protein and triglyceride synthesis and drug metabolism. Low fetal activity of endoplasmic reticulum–bound enzymes accounts for a relative inefficiency of xenobiotic (drug) metabolism. The Golgi apparatus is active in protein packaging and possibly in bile secretion. Hepatocyte peroxisomes are single-membrane-limited cytoplasmic organelles that contain enzymes such as oxidases and catalase and those that have a role in lipid and bile acid metabolism. Lysosomes contain numerous hydrolases that have a role in intracellular digestion. The hepatocyte cytoskeleton, composed of actin and other filaments, is distributed throughout the cell and concentrated near the plasma membrane. Microfilaments and microtubules have a role in receptor-mediated endocytosis, in bile secretion, and in maintaining hepatocyte architecture and motility.

**METABOLIC FUNCTIONS OF THE LIVER**

**Carbohydrate Metabolism**

The liver regulates serum glucose levels closely via several processes, including storage of excess carbohydrate as glycogen, a polymer of glucose readily hydrolyzed to glucose during fasting. To maintain serum glucose levels, hepatocytes produce free glucose by either gluconeogenesis or gluconeogenesis. Immediately after birth, an infant is dependent on hepatic gluconeogenesis. Gluconeogenic activity is present at a low level in the fetal liver and increases rapidly after birth. Fetal glycogen synthesis begins at about the 9th wk of gestation, with glycogen stores most rapidly accumulated near term, when the liver contains 2-3 times the amount of glycogen of adult liver. Most of this stored glycogen is used in the immediate postnatal period. Reaccumulation is initiated at about the 2nd wk of postnatal life, and glycogen stores reach adult levels at approximately the 3rd wk in healthy full-term infants. In preterm infants, serum glucose levels fluctuate in part because efficient regulation of the synthesis, storage, and degradation of glycogen develops only near the end of full-term gestation. Dietary carbohydrates such as galactose are converted to glucose, but there is a substantial dependence on gluconeogenesis for glucose in early life, especially if glycogen stores are limited.

**Protein Metabolism**

During the rapid fetal growth phase, specific decarboxylases that are rate limiting in the biosynthesis of physiologically important polyamines have higher activities than in the mature liver. The rate of synthesis of albumin and secretory proteins in the developing liver parallels the quantitative changes in endoplasmic reticulum. Synthesis of albumin appears at approximately the 7th-8th wk in the human fetus and increases in inverse proportion to that of α-fetoprotein, which is the dominant fetal protein. By the 3rd-4th mo of gestation, the fetal liver is able to produce fibrinogen, transferrin, and low-density lipoproteins. From this period on, fetal plasma contains each of the major protein classes at concentrations considerably below those achieved at maturity.

The postnatal patterns of protein synthesis vary with the class of protein. Lipoproteins of each class rise abruptly in the 1st wk after birth to reach levels that vary little until puberty. Albumin concentrations are low in a neonate (<2.5 g/dL), reaching adult levels (~3.5 g/dL) after several months. Levels of ceruloplasmin and complement factors increase slowly to adult values in the 1st yr. In contrast, transferrin levels at birth are similar to those of an adult, decline for 3-5 mo, and rise thereafter to achieve their final concentrations. Low levels of activity of specific proteins have implications for the nutrition of an infant. A low level of cystathionine γ-lyase (cystathionase) activity impairs the trans-sulfuration pathway by which dietary methionine is converted to cysteine. Consequently, the latter must be supplied in the diet. Similar dietary requirements might exist for other sulfur-containing amino acids, such as taurine.

**Lipid Metabolism**

Fatty acid oxidation provides a major source of energy in early life, complementing gluconeogenesis and gluconeogenesis. Newborn infants are relatively intolerant of prolonged fasting, owing in part to a restricted capacity for hepatic ketogenesis. Rapid maturation of the ability of the liver to oxidize fatty acid occurs in the 1st few days of life. Milk provides the major source of calories in early life; this high-fat, low-carbohydrate diet mandates active gluconeogenesis to maintain blood glucose levels. When the glucose supply is limited, ketone body production from endogenous fatty acids can provide energy for hepatic gluconeogenesis and an alternative fuel for brain metabolism. When carbohydrates are in excess, the liver produces triglycerides. Metabolic processes involving lipids and lipoproteins are
predominantly hepatic; liver immaturity or disease affects lipid concentrations and lipoproteins.

**Biotransformation**

Newborn infants have a decreased capacity to metabolize and detoxify certain drugs, owing to underdevelopment of the hepatic microsomal component that is the site of the specific oxidative, reductive, hydrolytic, and conjugation reactions required for these biotransformations. The major components of the monoxygenase system, such as cytochrome P450, cytochrome-c reductase, and the reduced form of nicotinamide-adenine dinucleotide phosphate, are present in low concentrations in fetal microsomal preparations. In full-term infants, hepatic uridine diphosphate glucuronosyltransferase and enzymes involved in the oxidation of polycyclic aromatic hydrocarbons are expressed at very low levels.

Age-related differences in pharmacokinetics vary from compound to compound. The half-life of acetaminophen in a newborn is similar to that of an adult, whereas theophylline has a half-life of approximately 100 hr in a premature infant, as compared to 5-6 hr in an adult. These differences in metabolism, as well as factors such as binding to plasma proteins and renal clearance, determine appropriate drug dosage to maximize effectiveness and to avoid toxicity. Dramatic examples of the susceptibility of newborn infants to drug toxicity are the responses to chloramphenicol (the “gray baby” syndrome) or to benzoil alcohol and its metabolic products, which involve ineffective glucuronide and glycine conjugation, respectively. The low concentrations of antioxidants (vitamin E, superoxide dismutase, glutathione peroxidase) in the fetal and early newborn liver lead to increased susceptibility to deleterious effects of oxygen toxicity and oxidant injury through lipid peroxidation.

Conjugation reactions, which convert drugs or metabolites into water-soluble forms that can be eliminated in bile, are also catalyzed by hepatic microsomal enzymes. Newborn infants have decreased activity of hepatic uridine diphosphate glucuronosyltransferase, which converts unconjugated bilirubin to the readily excreted glucuronide conjugate and is the rate-limiting enzyme in the excretion of bilirubin. There is rapid postnatal development of transferase activity irrespective of gestational age, which suggests that birth-related, rather than age-related, factors are of primary importance in the postnatal development of activity of this enzyme. Microsomal activity can be stimulated by administration of phenobarbital, rifampin, or other inducers of cytochrome P450. Alternatively, drugs such as cimetidine can inhibit microsomal P450 activity.

**Hepatic Excretory Function**

Hepatic excretory function and bile flow are closely related to hepatic *bile acid* excretion and enterohepatic recirculation. Bile acids, the major products of cholesterol degradation, are incorporated into mixed micelles with cholesterol and phospholipid. These micelles act as an efficient vehicle for solubilization and intestinal absorption of lipophilic compounds, such as dietary fats and fat-soluble vitamins. Secretion of bile acids by the liver cells is the major determinant of bile flow in the mature animal. Accordingly, maturity of bile acid metabolic processes affects overall hepatic excretory function, including biliary excretion of endogenous and exogenous compounds.

In humans, the 2 primary bile acids, cholic acid and chenodeoxycholic acid, are synthesized in the liver. Before excretion, they are conjugated with glycine and taurine. In response to a meal, contraction of the gallbladder delivers bile acids to the intestine to assist in fat digestion and absorption. Aftermediating fat digestion, the bile acids themselves are reabsorbed from the terminal ileum through specific active transport processes. They return to the liver via portal blood, are taken up by liver cells, and are reexcreted in bile. In an adult, this enterohepatic circulation involves 90-95% of the circulating bile acid pool. Bile acids that escape ileal reabsorption reach the colon, where the bacterial flora, through dehydroxylation and deconjugation, produce the secondary bile acids, deoxycholate and lithocholate. In an adult, the composition of bile reflects the excretion of the primary and also the secondary bile acids, which are reabsorbed from the distal intestinal tract.

Intraluminal concentrations of bile acids are low in newborn infants and increase rapidly after birth. The expansion of the bile acid pool is critical because bile acids are required to stimulate bile flow and absorb lipids, a major component of the diet of a newborn. Nuclear receptors, such as farnesoid X receptor, control intrahepatic bile acid homeostasis through several mechanisms, including regulation of expression of the genes encoding 2 key proteins, cholesterol 7α-hydroxylase (CYP7A1) and bile salt export pump (BSEP). These proteins are critical for bile acid synthesis and canalicular secretion, respectively. Neonatal expression of these nuclear receptors varies depending on the studied animal model and is largely unknown for humans.

Because of inefficient ileal reabsorption of bile acids and the low rate of hepatic clearance of bile acids from portal blood, serum concentrations of bile acids are commonly elevated in healthy newborns, often to levels that would suggest liver disease in older persons. Transient phases of “physiologic cholestasis” and “physiologic steatorrhea” can often be observed in low birthweight infants and in full-term infants following perinatal stress, such as hypoxia or infection, but are otherwise uncommon in healthy full-term newborns.

Many of the processes related to immaturity of the newborn in liver morphogenesis and function as discussed earlier are implied in the increased susceptibility of infants to liver disease associated with parenteral nutrition. The reduced bile salt pool, hepatic glutathione depletion, and deficient sulfation contribute to production of toxic lithocholic bile acids and cholestasis, whereas deficiencies of essential amino acids, including taurine and cysteine, and excessive lipid infusion can lead to hepatic steatosis in these infants. Beyond the neonatal period, disturbances in bile acid metabolism may be responsible for diverse effects on hepatobiliary and intestinal function (Table 354-2).

**Table 354-2** Causes of Impaired Bile Acid Metabolism and Enterohepatic Circulation

| DEFECTIVE BILE ACID SYNTHESIS OR TRANSPORT |
| Inborn errors of bile acid synthesis (reductase deficiency, isomerase deficiency) |
| Progressive familial intrahepatic cholestasis (PFIC1, PFIC2, PFIC3) |
| Intrahepatic cholestasis (neonatal hepatitis) |
| Acquired defects in bile acid synthesis secondary to severe liver disease |

| ABNORMALITIES OF BILE ACID DELIVERY TO THE BOWEL |
| Cystic fibrosis |
| External bile fistula |
| Drug-induced entrapment of bile acids in intestinal lumen (e.g., cholestyramine) |

| LOSS OF ENTEROHEPATIC CIRCULATION OF BILE ACIDS |
| External bile fistula |
| Small bowel bacterial overgrowth syndrome (with bile acid precipitation, increased jejunal absorption, and “short-circuiting”) |

| BILE ACID MALABSORPTION |
| Primary bile acid malabsorption (absent or inefficient ileal active transport) |
| Secondary bile acid malabsorption |
| Ileal disease or resection |
| Cystic fibrosis |

| DEFECTIVE UPTAKE OR ALTERED INTRACELLULAR METABOLISM |
| Parenchymal disease (acute hepatitis, cirrhosis) |
| Regurgitation from cells |
| Portosystemic shunting |
| Cholestasis |

PART XVIII  THE DIGESTIVE SYSTEM

Chapter 355

Manifestations of Liver Disease

James E. Squires and William F. Balistreri

PATHOLOGIC MANIFESTATIONS

Alterations in hepatic structure and function can be acute or chronic, with varying patterns of reaction of the liver to cell injury. Hepatocyte injury can be caused by viral infection, drugs or toxins, hypoxia, immunologic disorders, or inborn errors of metabolism. The injury results in inflammatory cell infiltration or cell death (necrosis), which may be followed by a healing process of scar formation (fibrosis) and, potentially, nodule formation (regeneration). Cirrhosis is the end result of any progressive liver disease.

Cholestasis is an alternative or concomitant response to injury caused by extrahepatic or intrahepatic obstruction to bile flow. Substances that are normally excreted in bile, such as conjugated bilirubin, cholesterol, bile acids, and trace elements, accumulate in serum. Bile pigment accumulation in liver parenchyma can be seen in liver biopsy specimens. In extrahepatic obstruction, bile pigment may be visible in the intralobular bile ducts or throughout the parenchyma as bile lakes or infarcts. In intrahepatic cholestasis, an injury to hepatocytes or an alteration in hepatic physiology leads to a reduction in the rate of secretion of solute and water. Likely causes include alterations in enzymatic or canalicular transporter activity, permeability of the bile canalicular apparatus, organelles responsible for bile secretion, or ultrastructure of the cytoskeleton of the hepatocyte. The end result can be clinically indistinguishable from obstructive cholestasis.

Cirrhosis, defined histologically by the presence of bands of fibrous tissue that link central and portal areas and form parenchymal nodules, is a potential end stage of any acute or chronic liver disease. Cirrhosis can be macronodular, with nodules of various sizes (up to 5 cm) separated by broad septa, or micronodular, with nodules of uniform size (<1 cm) separated by fine septa; mixed forms occur. The progressive scarring of cirrhosis results in altered hepatic blood flow, with further impairment of liver cell function. Increased intrahepatic resistance to portal blood flow leads to portal hypertension.

The liver can be secondarily involved in neoplastic (metastatic) and nonneoplastic (storage diseases, fat infiltration) processes, as well as a number of systemic conditions and infectious processes. The liver can be affected by chronic passive congestion (congestive heart failure) or acute hypoxia, with hepatocellular damage.

CLINICAL MANIFESTATIONS

Hepatomegaly

Enlargement of the liver can be caused by several mechanisms (Table 355-1). Normal liver size estimations are based on age-related clinical indices, such as the degree of extension of the liver edge below the costal margin, the span of dullness to percussion, or the length of the vertical axis of the liver, as estimated from imaging techniques. In children, the normal liver edge can be felt up to 2 cm below the right costal margin. In a newborn infant, extension of the liver edge more than 3.5 cm below the costal margin in the right midclavicular line suggests hepatic enlargement. Measurement of liver span is carried out by percussing the upper margin of dullness and by palpating the lower edge in the right midclavicular line. This may be more reliable than an extension of the liver edge alone. The 2 measurements may correlate poorly.

The liver span increases linearly with body weight and age in both sexes, ranging from approximately 4.5-5.0 cm at 1 wk of age to approximately 7.8 cm in boys and 6.0-6.5 cm in girls by 12 yr of age. The lower edge of the right lobe of the liver extends downward (Riedel lobe) and can normally be palpated as a broad mass in some people. An

</tbody>
</table>
enlarged left lobe of the liver is palpable in the epigastrium of some patients with cirrhosis. Downward displacement of the liver by the diaphragm (hyperinflation) or thoracic organs can create an erroneous impression of hepatomegaly.

Examination of the liver should note the consistency, contour, tenderness, and presence of any masses or bruits, as well as assessment of spleen size. Documentation of the presence of ascites and any stigmata of chronic liver disease is important.

Ultrasound is useful in assessment of liver size and consistency, as well as gallbladder size. Gallbladder length normally varies from 1.5-5.5 cm (average: 3 cm) in infants to 4-8 cm in adolescents; width ranges from 0.5-2.5 cm for all ages. Gallbladder distention may be seen in infants with sepsis. The gallbladder is often absent in infants with biliary atresia.

Jaundice (Icterus)
Yellow discoloration of the sclera, skin, and mucous membranes is a sign of hyperbilirubinemia (see Chapter 102.3). Clinically apparent jaundice in children and adults occurs when the serum concentration of bilirubin reaches 2-3 mg/dL (34-51 µmol/L); the neonate might not appear icteric until the bilirubin level is >5 mg/dL (>85 µmol/L). Jaundice may be the earliest and only sign of hepatic dysfunction. Liver disease must be suspected in the infant who appears only mildly jaundiced but has dark urine or acholic (light-colored) stools. Immediate evaluation to establish the cause is required.

Measurement of the total serum bilirubin concentration allows quantitation of jaundice. Bilirubin occurs in plasma in 4 forms: unconjugated bilirubin tightly bound to albumin; free or unbound bilirubin (the form responsible for kernicterus, because it can cross cell membranes); conjugated bilirubin (the only fraction to appear in urine); and δ fraction (bilirubin covalently bound to albumin), which appears in serum when hepatic excretion of conjugated bilirubin is impaired in patients with hepatobiliary disease. The δ fraction permits conjugated bilirubin to persist in the circulation and delays resolution of jaundice. Although the terms direct and indirect bilirubin are used equivalently with conjugated and unconjugated bilirubin, this is not quantitatively correct, because the direct fraction includes both conjugated bilirubin and δ bilirubin.

Investigation of jaundice in an infant or older child must include determination of the accumulation of both unconjugated and conjugated bilirubin. Unconjugated hyperbilirubinemia might indicate increased production, hemolysis, reduced hepatic removal, or altered metabolism of bilirubin (Table 355-2). Conjugated hyperbilirubinemia reflects decreased excretion by damaged hepatic parenchymal cells or disease of the biliary tract, which may be a result of obstruction, sepsis, toxins, inflammation, and genetic or metabolic disease (Table 355-3).

Pruritus
Intense generalized itching can occur in patients with chronic liver disease often in association with cholestasis (conjugated hyperbilirubinemia). Symptoms can be generalized or localized (commonly to palms and soles), are usually worse at night, are exacerbated with stress and heat, and are relieved by cool temperatures. Pruritus is unrelated to the degree of hyperbilirubinemia; deeply jaundiced patients can be asymptomatic. Although retained components of bile are likely important, the cause is probably multifactorial, as evidenced by the symptomatic relief of pruritus after administration of various therapeutic agents including bile acid-binding agents (cholestyramine), choleretic agents (ursodeoxycholic acid), opiate antagonists, antihistamines, and antibiotics. Plasmapheresis, molecular adsorbent recirculating system therapy, and surgical diversion of bile (partial external biliary diversion) have been used in attempts to provide relief for medically refractory pruritus.

Spider Angiomas
Vascular spiders (telangiectasias), characterized by central pulsating arterioles from which small, wiry venules radiate, may be seen in patients with chronic liver disease; these are usually most prominent

</table>

in the superior vena cava distribution area (on the face and chest). Their size varies between 1 and 10 mm and they exhibit central clearing with pressure. They presumably reflect altered estrogen metabolism in the presence of hepatic dysfunction.

**Palmar Erythema**

Blotchy erythema, most noticeable over the thenar and hypothenar eminences and on the tips of the fingers, is also noted in patients with chronic liver disease. Abnormal serum estradiol levels and regional alterations in peripheral circulation have been identified as possible causes.

**Xanthomas**

The marked elevation of serum cholesterol levels (to >500 mg/dL) associated with some forms of chronic cholestasis can cause the deposition of lipid in the dermis and subcutaneous tissue. Brown nodules can develop, first over the extensor surfaces of the extremities; rarely, xanthelasma of the eyelids develops.

**Portal Hypertension**

Portal hypertension occurs when there is increased portal resistance and/or increased portal flow. The portal system drains the splanchnic area (abdominal portion of the gastrointestinal tract, pancreas, and spleen) into the hepatic sinusoids. Normal portal pressure is between 3 and 6 mm Hg. Portal hypertension is defined as a portal pressure greater than 10 mm Hg. Clinically significant portal hypertension exists when pressure exceeds a threshold of 12 mm Hg or greater. Portal hypertension is the main complication of cirrhosis, directly responsible for 2 of its most common and potentially lethal complications: ascites and variceal hemorrhage.

**Ascites**

Ascites is a consequence of increased hydrostatic and osmotic pressures within the hepatic and mesenteric capillaries resulting in transfer of fluid from the blood vessels to the lymphatics that overcomes the drainage capacity of the lymphatic system. Ascites can also be associated with nephrotic syndrome and other urinary tract abnormalities, metabolic diseases (such as lysosomal storage diseases), congenital or acquired heart disease, and hydrops fetalis. Factors favoring the intraabdominal accumulation of fluid include decreased plasma colloid osmotic pressure, increased capillary hydrostatic pressure, increased ascitic colloid osmotic fluid pressure, and decreased ascitic fluid hydrostatic pressure. Abnormal renal sodium retention must be considered.
Gastrointestinal Bleeding
Chronic liver disease may manifest as gastrointestinal hemorrhage. Bleeding may result from portal hypertensive gastropathy, gastric antral vascular ectasia, or varix rupture. Variceal hemorrhage is classically from an esophageal origin but may be caused by gastric, duodenal, peristomial, or rectal varices. Variceal hemorrhage results from increased pressure within the varix, which leads to changes in the diameter of the varix and increased wall tension. When the variceal wall strength is exceeded, physical rupture of the varix results. Given the high blood flow and pressure in the portosystemic collateral system, coupled with the lack of a natural mechanism to tamponade variceal bleeding, the rate of hemorrhage can be striking.

Encephalopathy
Hepatic encephalopathy can involve any neurologic function, and it can be prominent or present in subtle forms such as deterioration of school performance, sleep disturbances, depression, or emotional outbursts. It can be recurrent and precipitated by intercurrent illness, drugs, bleeding, or electrolyte and acid-base disturbances. The appearance of hepatic encephalopathy depends on the presence of portosystemic shunting, alterations in the blood-brain barrier, and the interactions of toxic metabolites with the central nervous system. Postulated causes include altered ammonia metabolism, synergistic neurotoxins, decreased cerebral oxygen metabolism and blood flow, or false neurotransmitters with plasma amino acid imbalance.

Endocrine Abnormalities
Endocrine abnormalities are more common in adults with hepatic disease than in children. They reflect alterations in hepatic synthetic, storage, and metabolic functions, including those concerned with hormonal metabolism in the liver. Proteins that bind hormones in plasma are synthesized in the liver, and steroid hormones are conjugated in the liver and excreted in the urine; failure of such functions can have clinical consequences. Endocrine abnormalities can also result from malnutrition or specific deficiencies.

Renal Dysfunction
Systemic disease or toxins can affect the liver and kidneys simultaneously, or parenchymal liver disease can produce secondary impairment of renal function. In hepatobiliary disorders, there may be renal alterations in sodium and water economy, impaired renal concentrating ability, and alterations in potassium metabolism. Ascites in patients with cirrhosis may be related to inappropriate retention of sodium by the kidneys and expansion of plasma volume, or it may be related to sodium retention mediated by diminished effective plasma volume. Hepatorenal syndrome is defined as functional renal failure in patients with end-stage liver disease. The pathophysiology of hepatorenal syndrome is related to splanchnic vasodilation, mesenteric angiogenesis, and decreased effective blood volume with resulting decreased renal perfusion. The hallmark is intense renal vasoconstriction (mediated by hemodynamic, humoral, or neurogenic mechanisms) with coexistent systemic vasodilation. The diagnosis is supported by the findings of oliguria (<1 mL/kg/day), a characteristic pattern of urine electrolyte abnormalities (urine sodium <10 mEq/L, fractional excretion of sodium of 1%, urine:plasma creatinine ratio <10, and normal urinary sediment), absence of hypovolemia, and exclusion of other kidney pathology. The best treatment of hepatorenal syndrome is timely liver transplantation, because complete renal recovery can be expected.

Pulmonary Involvement
Hepatopulmonary syndrome is characterized by the typical triad of hypoxemia, intrapulmonary vascular dilations, and liver disease. There is intrapulmonary right-to-left shunting of blood resulting from enlarged pulmonary vessels that prevents red blood cells traveling through the center of the vessel adequate exposure to oxygen-rich alveoli. Shunting of vasodilatory mediators from the mesentery away from the liver is thought to contribute. It should be suspected and investigated in the child with chronic liver disease with history of shortness of breath or exercise intolerance and clinical examination findings of cyanosis (particularly of the lips and fingers), digital clubbing, and oxygen saturations <96%, particularly in the upright position. Treatment is timely liver transplantation; resolution of pulmonary involvement usually follows.

Portopulmonary hypertension is a condition characterized by an increase in the resistance to pulmonary arterial blood flow in the setting of portal hypertension. It is defined by a pulmonary arterial pressure >25 mm Hg at rest and above 30 mm Hg with exercise, elevated pulmonary vascular resistance with pulmonary arterial occlusion pressure, or a left-ventricular end-diastolic pressure of <15 mm Hg. Although the pathophysiology is unclear, symptoms suggesting a diagnosis include exertional dyspnea, fatigue, syncope, palpitations, and chest pain.

Recurrent Cholangitis
Ascending infection of the biliary system is often seen in pediatric cholestatic disorders, most commonly because of Gram-negative enteric organisms, such as Escherichia coli, Klebsiella, Pseudomonas, and Enterococcus. Liver transplantation is the definitive treatment for recurrent cholangitis, especially when medical therapy is not effective.

Miscellaneous Manifestations of Liver Dysfunction
Nonspecific signs of acute and chronic liver disease include anorexia, which often affects patients with anicteric hepatitis and with cirrhosis associated with chronic cholestasis; abdominal pain or distention resulting from ascites, spontaneous peritonitis, or visceromegaly; malnutrition and growth failure; and bleeding, which may be a result of altered synthesis of coagulation factors (biliary obstruction with vitamin K deficiency or excessive hepatic damage) or to portal hypertension with hypersplenism. In the presence of hypersplenism, there can be decreased synthesis of specific clotting factors, production of qualitatively abnormal proteins, or alterations in platelet number and function. Altered drug metabolism can prolong the biologic half-life of commonly administered medications.

355.1 Evaluation of Patients with Possible Liver Dysfunction
James E. Squires and William F. Balistreri

Adequate evaluation of an infant, child, or adolescent with suspected liver disease involves an appropriate and accurate history, a carefully performed physical examination, and skillful interpretation of signs and symptoms. Further evaluation is aided by judicious selection of diagnostic tests, followed by the use of imaging modalities or a liver biopsy. Most of the so-called liver function tests do not measure specific hepatic functions: a rise in serum aminotransferase levels reflects liver cell injury, an increase in immunoglobulin levels reflects an immunologic response to injury, or an elevation in serum bilirubin levels can reflect any of several disturbances of bilirubin metabolism (see Tables 355-2 and 355-3). Any single biochemical assay provides limited information, which must be placed in the context of the entire clinical picture. The most cost-efficient approach is to become familiar with the rationale, implications, and limitations of a selected group of tests so that specific questions can be answered. Young infants with cholestatic jaundice should be evaluated promptly to identify patients needing surgical intervention.

For a patient with suspected liver disease, evaluation addresses the following issues in sequence: Is liver disease present? If so, what is its nature? What is its severity? Is specific treatment available? How can we monitor the response to treatment? What is the prognosis?
**Bibliography**

BIOCHEMICAL TESTS

Laboratory tests commonly used to screen for or to confirm a suspicion of liver disease include measurements of serum aminotransferase, bilirubin (total and fractionated), and alkaline phosphatase (AP) levels, as well as determinations of prothrombin time (PT) or international normalized ratio (INR) and albumin level. These tests are complementary, providing an estimation of synthetic and excretory functions, and might suggest the nature of the disturbance (inflammation or cholestasis).

The severity of the liver disease may be reflected in clinical signs or biochemical alterations. Clinical signs include encephalopathy, variceal hemorrhage, worsening jaundice, apparent shrinkage of liver mass owing to massive necrosis, or onset of ascites. Biochemical alterations include hypoglycemia, acidosis, hyperammonemia, electrolyte imbalance, continued hyperbilirubinemia, marked hypoalbuminemia, or a prolonged PT or INR that is unresponsive to parenteral administration of vitamin K.

Acute liver cell injury (parenchymal disease) caused by viral hepatitis, drug- or toxin-induced liver disease, shock, hypoxemia, or metabolic disease is best reflected by a marked increase in serum aminotransferase levels. Cholestasis (obstructive disease) involves regurgitation of bile components into serum; the serum levels of total and conjugated bilirubin and serum bile acids are elevated. Elevations in serum AP, 5′ nucleotidase, and γ-glutamyl transpeptidase levels are also sensitive indicators of obstruction or inflammation of the biliary tract. Fractionation of the total serum bilirubin level into conjugated and unconjugated bilirubin fractions helps to distinguish between elevations caused by processes such as hemolysis and those caused by hepatic dysfunction. A predominant elevation in the conjugated bilirubin level provides a relatively sensitive index of hepatocellular disease or hepatic excretory dysfunction.

Alanine aminotransferase (ALT, serum glutamate pyruvate transaminase) is liver specific, whereas aspartate aminotransferase (AST, serum glutamic-oxaloacetic transaminase) is derived from other organs in addition to the liver. The most marked rises of AST and ALT levels can occur with acute hepatocellular injury; a several thousand-fold elevation can result from acute viral hepatitis, toxic injury, hypoxia, or hypoperfusion. After blunt abdominal trauma, parallel elevations in aminotransferase levels can provide an early clue to hepatic injury. A differential rise or fall in AST and ALT levels sometimes provides useful information. In acute hepatitis, the rise in ALT may be greater than the rise in AST. In alcohol-induced liver injury, fulminant echovirus infection, and various metabolic diseases, more predominant rises in the AST level are reported. In chronic liver disease or in intrahepatic and extrahepatic biliary obstruction, AST and ALT elevations may be less marked. Elevated serum aminotransferase levels are seen in patients with nonalcoholic fatty liver disease and nonalcoholic steatohepatitis (NASH), the notable characteristic is histology similar to alcoholic-induced liver injury in the absence of alcohol abuse.

Hepatic synthetic function is reflected in serum albumin and protein levels and in the PT or INR. Examination of serum globulin concentration and of the relative amounts of the globulin fractions may be helpful. Patients with autoimmune hepatitis often have high γ-globulin levels and increased titer of anti–smooth muscle, antinuclear, and anti–liver-kidney-microsome antibodies. Antimitochondrial antibodies may also be found in patients with autoimmune hepatitis. A resurgence in α-fetoprotein levels can suggest hepatoma, hepatoblastoma, or hereditary tyrosinemia. Hypoalbuminemia caused by depressed synthesis can complicate severe liver disease and serve as a prognostic factor. Deficiencies of factor V and of the vitamin K–dependent factors (II, VII, IX, and X) can occur in patients with severe liver disease or fulminating hepatic failure. If the PT or INR is prolonged as a result of intestinal malabsorption of vitamin K (resulting from cholestasis) or decreased nutritional intake of vitamin K, parenteral administration of vitamin K should correct the coagulopathy, leading to normalization within 12–24 hr. Unresponsiveness to vitamin K suggests severe hepatic disease. Persistently low levels of factor VII are evidence of a poor prognosis in fulminating liver disease.

Interpretation of results of biochemical tests of hepatic structure and function must be made in the context of age-related changes. The activity of AP varies considerably with age. Normal growing children have significant elevations of serum AP activity originating from influx into serum of the isoenzyme that originates in bone, particularly in rapidly growing adolescents. An isolated increase in AP does not indicate hepatic or biliary disease if other liver tests are normal. Other enzymes such as 5′ nucleotidase and γ-glutamyl transpeptidase are increased in cholestatic conditions and may be more specific for hepatobiliary disease. 5′ Nucleotidase is not found in bone. γ-Glutamyl transpeptidase exhibits high enzyme activity in early life that declines rapidly with age. Cholesterol concentrations increase throughout life. Cholesterol levels may be markedly elevated in patients with intra- or extrahepatic cholestasis and decreased in severe acute liver disease such as hepatitis.

Interpretation of serum ammonia values must be carried out with caution because of variability in their physiologic determinants and the inherent difficulty in laboratory measurement.

LIVER BIOPSY

Liver biopsy combined with clinical data can suggest a cause for hepatocellular injury or cholestatic disease in most cases. Specimens of liver tissue can be used to determine a precise histologic diagnosis in patients with neonatal cholestasis, chronic hepatitis, nonalcoholic fatty liver disease or nonalcoholic steatohepatitis, metabolic liver disease, intrahepatic cholestasis, congenital hepatic fibrosis, or undefined portal hypertension. The sample may be subjected to enzyme analysis to detect inborn errors of metabolism and to analysis of stored material such as iron, copper, or specific metabolites. Liver biopsies can monitor responses to therapy or detect complications of treatment with potentially hepatotoxic agents, such as aspirin, antinfectives (minocycline, ketoconazole, isoniazid), antimitoblastes, antineoplastics, or anticonvulsant agents.

In infants and children, needle biopsy of the liver is easily accomplished percutaneously. The amount of tissue obtained, even in small infants, is usually sufficient for histologic interpretation and for biochemical analyses, if the latter are deemed necessary. Percutaneous liver biopsy can be performed safely in infants as young as 1 wk of age. Contraindications to the percutaneous approach include prolonged PT or INR; thrombocytopenia; suspicion of a vascular, cystic, or infectious lesion in the path of the needle; and severe ascites. If administration of fresh-frozen plasma or of platelet transfusions fails to correct a prolonged PT, INR, or thrombocytopenia, a tissue specimen can be obtained via alternative techniques. Considerations include either the open laparotomy (wedge) approach by a general surgeon or the transjugular approach under ultrasound and fluoroscopic guidance by an experienced pediatric interventional radiologist in an appropriately equipped fluoroscopy suite. The risk of development of a complication such as hemorrhage, hematoma, creation of an arteriovenous fistula, pneumothorax, or bile peritonitis is small.

HEPATIC IMAGING PROCEDURES

Various techniques help define the size, shape, and architecture of the liver and the anatomy of the intrahepatic and extrahepatic biliary trees. Although imaging might not provide a precise histologic and biochemical diagnosis, specific questions can be answered, such as whether hepatomegaly is related to accumulation of fat or glycogen or is caused by a tumor or cyst. These studies can direct further evaluation such as percutaneous biopsy and make possible prompt referral of patients with biliary obstruction to a surgeon. Choice of imaging procedure should be part of a carefully formulated diagnostic approach, with avoidance of redundant demonstrations by several techniques.

A plain x-ray study can suggest hepatomegaly, but a carefully performed physical examination gives a more reliable assessment of liver size. The liver might appear less dense than normal in patients with fatty infiltration or denser with deposition of heavy metals such as iron. A hepatic or biliary tract mass can displace an air-filled loop of bowel. Calcifications may be evident in the liver (parasitic or neoplasic disease), in the vasculature (portal vein thrombosis), or in the
gallbladder or biliary tree (gallstones). Collections of gas may be seen within the liver (abscess), biliary tract, or portal circulation (necrotizing enterocolitis).

Ultrasound provides information about the size, composition, and blood flow of the liver. Increased echogenicity is observed with fatty infiltration; mass lesions as small as 1-2 cm may be shown. Ultrasound has replaced cholangiography in detecting stones in the gallbladder or biliary tree. Even in neonates, ultrasound can assess gallbladder size, detect dilation of the biliary tract, and define a choledochal cyst. In infants with biliary atresia, ultrasound findings might include small or absent gallbladder; nonvisualization of the common duct; and presence of the triangular cord sign, a triangular or tubular-shaped echogenic density in the bifurcation of the portal vein, representing fibrous remnants at the porta hepatitis. Hypercholesterogenic hepatic parenchyma can be seen with metabolic disease (glycogen storage disease) or fatty liver (obesity, malnutrition, hyperalimentation, corticosteroids). In patients with portal hypertension, Doppler ultrasound can evaluate patency of the portal vein, demonstrate collateral circulation, and assess size of spleen and amount of ascites. Relatively small amounts of ascitic fluid can also be detected. The use of Doppler ultrasound has been helpful in determining vascular patency after liver transplantation.

CT scanning provides information similar to that obtained by ultrasound but is less suitable for use in patients younger than 2 yr of age because of the small size of structures, the paucity of intraabdominal fat for contrast, and the need for heavy sedation or general anesthesia. CT scan may be more accurate than ultrasound in detecting focal lesions such as tumors, cysts, and abscesses. When enhanced by contrast medium, CT scanning can reveal a neoplastic mass density only slightly different from that of a normal liver. When a hepatic tumor is suspected, CT scanning is the best method to define anatomic extent, solid or cystic nature, and vascularity. CT scanning can also reveal subtle differences in density of liver parenchyma, the average liver attenuation coefficient being reduced with fatty infiltration. MRI is a useful alternative that limits radiation exposure. Magnetic resonance cholangiography can be of value in differentiating biliary tract lesions. MRI with Eovist (gadobenate disodium) can assist in the detection and characterization of known or suspected focal liver lesions. In differentiating obstructive from nonobstructive cholestasis, CT scanning or MRI identifies the precise level of obstruction more often than ultrasound. Either CT scanning or ultrasound may be used to guide percutaneously placed fine needles for biopsies, aspiration of specific lesions, or cholangiography.

Elastography is a novel noninvasive method to assess for the development of hepatic fibrosis in patients with liver disease. Both ultrasound and MR methods of have been developed. These noninvasive techniques allow for monitoring fibrosis progression and development of cirrhosis, improved characterization of hepatic tumors, and prognostic stratification of diseases such as nonalcoholic fatty liver disease and nonalcoholic steatohepatitis.

Radionuclide scanning relies on selective uptake of a radiopharmaceutical agent. Commonly used agents include technetium-99m-labeled sulfur colloid, which undergoes phagocytosis by Kupffer cells; 99mTc- iminodiacetic acid agents, which are taken up by hepatocytes and excreted into bile in a fashion similar to bilirubin; and gallium-67, which is concentrated in inflammatory and neoplastic cells. The anatomic resolution possible with hepatic scintiscans is generally less than that obtained with CT scanning, MRI, or ultrasound.

The 99mTc-sulfur colloid scan can detect focal lesions (tumors, cysts, abscesses) >2-3 cm in diameter. This modality can help to evaluate patients with possible cirrhosis and with patchy hepatic uptake and a shift of colloid uptake from liver to bone marrow.

Cholangiography, direct visualization of the intrahepatic and extrahepatic biliary tree after injection of opaque material, may be required in some patients to evaluate the cause, location, or extent of biliary obstruction. Percutaneous transhepatic cholangiography with a fine needle is the technique of choice in infants and young children. The likelihood of opacifying the biliary tract is excellent in patients in whom CT scanning, MRI, or ultrasound demonstrates dilated ducts.

Percutaneous transhepatic cholangiography has been used to outline the biliary ductal system.

Endoscopic retrograde cholangiopancreatography is an alternative method of examining the bile ducts in older children. The papilla of Vater is cannulated under direct vision through a fiberoptic endoscope, and contrast material is injected into the biliary and pancreatic ducts to outline the anatomy. The advantage of endoscopic retrograde cholangiopancreatography is that it allows therapeutic interventions of the extrahepatic biliary tree (stone extraction, stent placement, etc.). Selective angiography of the celiac, superior mesenteric, or hepatic artery can be used to visualize the hepatic or portal circulation. Both arterial and venous circulatory systems of the liver can be examined. Angiography is often required to define the blood supply of tumors before surgery and is useful in the study of patients with known or presumed portal hypertension. The patency of the portal system, the extent of collateral circulation, and the caliber of vessels under consideration for a shunting procedure can be evaluated. MRI can provide similar information.

**DIAGNOSTIC APPROACH TO INFANTS WITH JAUNDICE**

Well-appearing infants can have cholestatic jaundice. Biliary atresia and neonatal hepatitis are the most common causes of cholestasis in early infancy. Biliary atresia portends a poor prognosis unless it is identified early. The best outcome for this disorder is with early surgical reconstruction (45-60 days of age). History, physical examination, and the detection of a conjugated hyperbilirubinemia via examination of total and direct bilirubin are the first steps in evaluating the jaundiced infant (Fig. 355-1). Consultation with a pediatric gastroenterologist should be sought early in the course of the evaluation.

Bibliography is available at Expert Consult.
Bibliography
Neonatal cholestasis is defined biochemically as prolonged elevation of the serum levels of conjugated bilirubin beyond the 1st 14 days of life. Jaundice that appears after 2 wk of age, continues to progress, or does not resolve at this time should be evaluated and a conjugated bilirubin level determined. Cholestasis in a newborn can be caused by infectious, genetic, metabolic, or undefined abnormalities giving rise to mechanical obstruction of bile flow or to functional impairment of hepatic excretory function and bile secretion (see Table 355-3). Mechanical lesions include stricture or obstruction of the common bile duct; biliary atresia is the prototypic obstructive abnormality. Functional impairment of bile secretion can result from congenital defects or damage to liver cells or to the biliary secretory apparatus.

Neonatal cholestasis can be divided into extrahepatic and intrahepatic disease (Fig. 356-1). The clinical features of any form of cholestasis are similar. In an affected neonate, the diagnosis of certain entities, such as galactosemia, sepsis, or hypothyroidism, is relatively simple and a part of most neonatal screening programs. In most cases, the cause of cholestasis is more obscure. Differentiation among biliary atresia and idiopathic neonatal hepatitis is particularly difficult.
**Figure 356-1 Neonatal cholestasis.** Conceptual approach to the group of diseases presenting as cholestasis in the neonate. There are areas of overlap: patients with biliary atresia might have some degree of intrahepatic injury. Patients with “idiopathic” neonatal hepatitis might, in the future, be determined to have a primary metabolic or viral disease.

### MECHANISMS

Metabolic liver disease caused by inborn errors of bile acid metabolism or transport is associated with accumulation of atypical toxic primitive bile acids and failure to produce normal choleretic and trophic bile acids. The clinical and histologic manifestations are nonspecific and are similar to those in other forms of neonatal hepatobiliary injury. Autoimmune mechanisms may also be responsible for some of the enigmatic forms of neonatal liver injury.

Some of the histologic manifestations of hepatic injury in early life are not seen in older patients. Giant cell transformation of hepatocytes occurs commonly in infants with cholestasis and can occur in any form of neonatal liver injury. It is more common and more severe in intrahepatic forms of cholestasis. The clinical and histologic findings that exist in patients with neonatal hepatitis and in those with biliary atresia are quite disparate; the basic process is an undefined initiating insult causing inflammation of the liver cells or of the cells within the biliary tract. If bile duct epithelium is the predominant site of disease, cholestasis (conjugated bilirubin elevation of any degree) in the neonate may be the initial manifestation of numerous effective sequence in a multistep process (Table 356-2). Although cholestasis in the neonate may be the initial manifestation of numerous and potentially serious disorders, the clinical manifestations are usually similar and provide very few clues about etiology. Affected infants have icterus, dark urine, light or acholic stools, and hepatomegaly, all resulting from decreased bile flow as a result of either hepatocyte injury or bile duct obstruction. Hepatic synthetic dysfunction can lead to hypoprothrombinemia and bleeding. Administration of vitamin K should be included in the initial treatment of cholestatic infants to prevent hemorrhage.

In contrast to unconjugated hyperbilirubinemia, which can be physiologic, cholestasis (conjugated bilirubin elevation of any degree) in the neonate is **always pathologic** and prompt differentiation is imperative. Thus the initial step is to identify the infant who has cholestasis. The next step is to recognize conditions that cause cholestasis and for which specific therapy is available to prevent further damage and avoid long-term complications such as sepsis, an endocrinopathy (hypothyroidism, panhypopituitarism), nutritional hepatotoxicity caused by a specific metabolic illness (galactosemia), or other metabolic diseases (tyrosinemia).

Hepatobiliary disease can be the initial manifestation of homozgyous α1-antitrypsin deficiency or of cystic fibrosis. Neonatal liver disease can also be associated with congenital syphilis and specific viral infections, notably echovirus and herpesviruses including

**EVALUATION**

The evaluation of the infant with jaundice should follow a logical, cost-effective sequence in a multistep process (Table 356-2). Although cholestasis in the neonate may be the initial manifestation of numerous and potentially serious disorders, the clinical manifestations are usually similar and provide very few clues about etiology. Affected infants have icterus, dark urine, light or acholic stools, and hepatomegaly, all resulting from decreased bile flow as a result of either hepatocyte injury or bile duct obstruction. Hepatic synthetic dysfunction can lead to hypoprothrombinemia and bleeding. Administration of vitamin K should be included in the initial treatment of cholestatic infants to prevent hemorrhage.

In contrast to unconjugated hyperbilirubinemia, which can be physiologic, cholestasis (conjugated bilirubin elevation of any degree) in the neonate is **always pathologic** and prompt differentiation is imperative. Thus the initial step is to identify the infant who has cholestasis. The next step is to recognize conditions that cause cholestasis and for which specific therapy is available to prevent further damage and avoid long-term complications such as sepsis, an endocrinopathy (hypothyroidism, panhypopituitarism), nutritional hepatotoxicity caused by a specific metabolic illness (galactosemia), or other metabolic diseases (tyrosinemia).

Hepatobiliary disease can be the initial manifestation of homozgyous α1-antitrypsin deficiency or of cystic fibrosis. Neonatal liver disease can also be associated with congenital syphilis and specific viral infections, notably echovirus and herpesviruses including
The prenatal diagnosis of Zellweger syndrome can allow analysis of cerebral gyration and myelination, facilitating the show an absence of peroxisomes. MRI performed in the 3rd trimester of gestation can detect hallmark features such as subcortical cysts, stippled calcifications of the patellas and greater trochanter, and abnormal head shape and unusual facies, hepatomegaly, renal cortical dysplasia, and intrahepatic cholestasis. Infants have severe, generalized hypotonia and markedly impaired motor milestones, with an increased risk of sudden death in the 1st mo. Affected infants usually present with episodic cholestasis and recurrent severe liver failure. Although recovery from neonatal iron storage disease either spontaneously or with medical therapy is unusual, the potential for histologic recovery with regression of fibrosis has been reported. The differential diagnosis includes familial hemophagocytic lymphohistiocytosis, mitochondrial respiratory chain disorders, galactosemia, tyrosinemia, viral hepatitis (HSV, CMV), congenital syphilis, and idiopathic neonatal hepatitis. In babies with familial neonatal cholestasis, the diagnosis is usually confirmed by buccal mucosal biopsy or MRI demonstrating extrahepatic siderosis in the reticuloendothelial system. Patients have multiorgan failure and shortened survival. Familial cases are reported, and repeated affected neonates in the same family are common. This is an alloimmune disorder with maternal antibodies directed against the fetal liver. Laboratory findings include hypoglycemia, hyperbilirubinemia, hypoalbuminemia, elevated ferritin and profound hypoprothrombinemia. Serum aminotransferase levels may be high initially but normalize with the progression of the disease. The diagnosis is usually confirmed by buccal mucosal biopsy or MRI demonstrating extrahepatic siderosis. The prognosis is poor; however, liver transplantation can be curative. Despite initially encouraging reports, the use of a combination of antioxidants and prostaglandin infusion with chelation might not uniformly improve outcome in patients with neonatal iron storage disease. Although recovery from neonatal iron storage disease is a rare autosomal recessive genetic disorder marked by progressive degeneration of the liver and kidneys (see Chapter 80.2). The incidence is estimated to be 1 in 100,000 births; the disease is usually fatal in 6-12 mo. Affected infants have severe, generalized hypotonia and markedly impaired neurologic function with psychomotor retardation. Patients have an abnormal head shape and unusual facies, hepatomegaly, renal cortical cysts, stippled calcifications of the patellas and greater trochanter, and ocular abnormalities. Hepatic cells on ultrastructural examination show an absence of peroxisomes. MRI performed in the 3rd trimester can allow analysis of cerebral gyration and myelination, facilitating the prenatal diagnosis of Zellweger syndrome.

Neonatal iron storage disease (neonatal hemochromatosis) is a rapidly progressive disease characterized by increased iron deposition in the liver, heart, and endocrine organs without increased iron stores in the reticuloendothelial system. Patients have multiorgan failure and shortened survival. Familial cases are reported, and repeated affected neonates in the same family are common. This is an alloimmune disorder with maternal antibodies directed against the fetal liver. Laboratory findings include hypoglycemia, hyperbilirubinemia, hypoalbuminemia, elevated ferritin and profound hypoprothrombinemia. Serum aminotransferase levels may be high initially but normalize with the progression of the disease. The diagnosis is usually confirmed by buccal mucosal biopsy or MRI demonstrating extrahepatic siderosis. The prognosis is poor; however, liver transplantation can be curative. Despite initially encouraging reports, the use of a combination of antioxidants and prostaglandin infusion with chelation might not uniformly improve outcome in patients with neonatal iron storage disease.

### INTRAHEPATIC CHOLESTASIS

**Neonatal Hepatitis**

The term neonatal hepatitis implies intrahepatic cholestasis (see Fig. 356-1), which has various forms (see Tables 356-1 and 356-3).

**Idiopathic neonatal hepatitis,** which can occur in either a sporadic or a familial form, is a disease of unknown cause. Patients with the sporadic form presumably have a specific yet undefined metabolic or viral disease. Familial forms, on the other hand, presumably reflect a genetic or metabolic aberration; in the past, patients with viral disease. Familial forms, on the other hand, presumably reflect a genetic or metabolic aberration; in the past, patients with familial forms of idiopathic neonatal hepatitis had a relatively good prognosis because more than 50% can spontaneously improve outcome in patients with neonatal iron storage disease.

**Aagenaes syndrome** is a form of idiopathic familial intrahepatic cholestasis associated with lymphedema of the lower extremities. The relationship between liver disease and lymphedema is not understood and may be attributable to decreased hepatic lymph flow or hepatic lymphatic hypoplasia. Aagenaes syndrome has a relatively good prognosis because more than 50% can spontaneously improve outcome in patients with neonatal iron storage disease.

**Zellweger (cerebrohepatorenal) syndrome** is a rare autosomal recessive genetic disorder marked by progressive degeneration of the liver and kidneys (see Chapter 80.2). The incidence is estimated to be 1 in 100,000 births; the disease is usually fatal in 6-12 mo. Affected infants have severe, generalized hypotonia and markedly impaired neurologic function with psychomotor retardation. Patients have an abnormal head shape and unusual facies, hepatomegaly, renal cortical cysts, stippled calcifications of the patellas and greater trochanter, and ocular abnormalities. Hepatic cells on ultrastructural examination show an absence of peroxisomes. MRI performed in the 3rd trimester can allow analysis of cerebral gyration and myelination, facilitating the prenatal diagnosis of Zellweger syndrome.

**Neonatal iron storage disease (neonatal hemochromatosis)** is a rapidly progressive disease characterized by increased iron deposition in the liver, heart, and endocrine organs without increased iron stores in the reticuloendothelial system. Patients have multiorgan failure and shortened survival. Familial cases are reported, and repeated affected neonates in the same family are common. This is a genetic disorder marked by progressive degeneration of the liver and kidneys (see Chapter 80.2). The incidence is estimated to be 1 in 100,000 births; the disease is usually fatal in 6-12 mo. Affected infants have severe, generalized hypotonia and markedly impaired neurologic function with psychomotor retardation. Patients have an abnormal head shape and unusual facies, hepatomegaly, renal cortical cysts, stippled calcifications of the patellas and greater trochanter, and ocular abnormalities. Hepatic cells on ultrastructural examination show an absence of peroxisomes. MRI performed in the 3rd trimester can allow analysis of cerebral gyration and myelination, facilitating the prenatal diagnosis of Zellweger syndrome.

**DISORDERS OF TRANSPORT, SECRETION, CONJUGATION, AND BIOSYNTHESIS OF BILE ACIDS**

**Progressive familial intrahepatic cholestasis type 1 (PFIC 1) or FIC1 disease** (formerly known as Byler disease) is a severe form of intrahepatic cholestasis. The disease was initially described in the Amish kindred of Jacob Byler. Affected patients present with steatorrhea, pruritus, vitamin D–deficient rickets, gradually developing cirrhosis, and low γ-glutamyl transpeptidase (GGT) levels. The absence of bile duct paucity and extrhepatic features differentiate this disorder from Alagille syndrome.

PFIC 1 (FIC1 deficiency) has been mapped to chromosome 18q12 and results from defect in the gene for FIC1 (ATP8B1; see Tables 356-3 and 356-4). FIC1 is a P-type adenosine triphosphatase that functions as aminophospholipid flippase, facilitating the transfer of phosphatidylcholine from the outer to the inner leaflet of the bile canalicular membrane. This protein is homologous to ATP8B2, which is involved in sphingolipid trafficking. FIC1 expression is restricted to the bile canalicular membrane, and its function is critical for maintaining the integrity of the canalicular membrane. Mutations in FIC1 result in increased cholestasis, bile duct paucity, and extrhepatic features, leading to the diagnosis of progressive familial intrahepatic cholestasis type 1.

serine and phosphatidyl ethanolamine from the outer to inner hemisphere of the cellular membrane. FIC1 might also play a role in intestinal bile acid absorption, as suggested by the high level of expression in the intestine. Defective FIC1 might also result in another form of intrahepatic cholestasis: benign recurrent intrahepatic cholestasis (BRIC) type 1. The disease is characterized by recurrent bouts of cholestasis, jaundice, and severe pruritus lasting from 2 wk to 6 mo; it can last up to 5 yr. The episodes vary from few episodes per year to 1 episode per decade and can profoundly affect the quality of life. Nonsense, frame shift, and deleterional mutations cause PFIC type 1; missense and split-type mutations result in BRIC type I. Typically, patients with BRIC type I have normal cholesterol and GGT levels.

PFIC type 2 (BSEP deficiency) is mapped to chromosome 2q24 and is similar to PFIC 1 but is present in non-Amish families (Middle Eastern and European). The disease results from defects in the canalicular adenosine triphosphate–dependent bile acid transporter BSEP (ABCB11). The progressive liver disease results from accumulation of bile acids secondary to reduction in canalicular bile acid secretion. Mutation in ABC11 is also described in another disorder, BRIC type 2, characterized by recurrent bouts of cholestasis.

In contrast to PFIC 1 and PFIC 2, patients with PFIC type 3 (MDR3 disease) have high levels of GGT. The disease results from defects in a canalicular phospholipids flipase, MDR3 (ABCB4), which results in deficient translocation of phosphatidylcholine across the canalicular membrane. Mothers who are heterozygous for this gene can develop intrahepatic cholestasis during pregnancy.

Familial hypercholanemia is characterized by elevated serum bile acid concentration, pruritus, failure to thrive, and coagulopathy. Familial hypercholanemia is a complex genetic trait associated with mutation of bile acid coenzyme A (CoA), amino acid N-acyltransferase (encoded by BAAT), as well as mutations in tight junction protein 2 (encoded by TJP 2, also known as ZO-2). Mutation of BAAT, which

is a bile acid–conjugating enzyme, abrogates the enzyme activity. Patients who are homozygous for this mutation have only unconjugated bile acids in their bile. Mutation of both BAAT and TJP2 can disrupt bile acid transport and circulation. Patients with familial hypercholestanemia usually respond to the administration of ursodeoxycholic acid.

Defective bile acid biosynthesis is postulated to be an initiating or perpetuating factor in neonatal cholestatic disorders; the hypothesis is that inborn errors in bile acid biosynthesis lead to absence of normal trophic or cholesteric primary bile acids and accumulation of atypical (hepatotoxic) metabolites. Inborn errors of bile acid biosynthesis cause acute and chronic liver disease; early recognition allows institution of targeted bile acid replacement, which reverses the hepatic injury. Several specific defects have been described:

- **Deficiency of Δ5-3-oxosteroid-5β reductase**, the 4th step in the pathway of cholesterol degradation to the primary bile acids, manifests with significant cholestasis and liver failure developing shortly after birth, with coagulopathy and metabolic liver injury resembling tyrosinemia. Hepatic histology is characterized by lobular disarray with giant cells, pseudocanicular transformation, and canalicular bile stasis. Mass spectrometry is required to document increased urinary bile acid excretion and the predominance of oxo-hydroxy and oxo-dihydroxy cholenoic acids. Treatment with cholic acid and ursodeoxycholic acid is associated with normalization of biochemical, histologic, and clinical features.

- **Deficiency of 3β-hydroxy-Δ5-steroid oxidoreductase (3β-HSD)**, the 2nd step in bile acid biosynthesis, causes progressive familial intrahepatic cholestasis. Affected patients usually have jaundice with increased aminotransferase levels and hepatomegaly; GGT levels and serum cholyglycine levels are normal. The histology is variable, ranging from giant cell hepatitis to chronic hepatitis. The diagnosis, suggested by mass spectrometry detection of C27 bile acids in urine, which retain the 3β-hydroxy-Δ5 structure, can be confirmed by determination of 3β-HSD activity in cultured fibroblasts using 7α-hydroxy-Δ5 cholesterol as a substrate. Primary bile acid therapy, administered orally to down regulate cholesterol 7α-hydroxylase activity, to limit the production of 3β-hydroxy-Δ5 bile acids, and to facilitate hepatic clearance, has been effective in reversing hepatic injury.

**BILE ACID–COENZYME A LIGASE DEFICIENCY**

Conjugation with the amino acids glycine and taurine is the final step in bile acid synthesis. Two enzymes catalyze the amidation of bile acids. In the first reaction, a CoA thioester is formed by the rate-limiting bile acid–CoA ligase. The other reaction involves the coupling of glycine or taurine and is catalyzed by a cytosolic bile acid–CoA:amino acid N-acyltransferase. Several patients with bile acid–CoA ligase deficiency have been reported. The patients present with conjugated hyperbilirubinemia, growth failure, or fat-soluble vitamin deficiency, and are identified with mutation of the bile acid–CoA ligase gene. Administration of conjugates of the primary bile acid, glycocholic acid, may be beneficial and can correct the fat-soluble vitamin malabsorption and improve growth.

**DISORDERS OF EMBRYOGENESIS**

Alagille syndrome (arteriohepatic dysplasia) is the most common syndrome with intrahepatic bile duct paucity. Bile duct “paucity” (often erroneously called intrahepatic biliary atresia) designates an absence or marked reduction in the number of interlobular bile ducts in the portal triads, with normal-size branches of portal vein and hepatic artery. Biopsy in early life often reveals an inflammatory process involving the bile ducts; subsequent biopsy specimens then show subidence of the inflammation, with residual reduction in the number and diameter of bile ducts, analogous to the “disappearing bile duct syndrome” noted in adults with immune-mediated disorders. Serial assessment of hepatic histology often suggests progressive destruction of bile ducts.

**Clinical manifestations** of Alagille syndrome are expressed in various degrees and can be nonspecific; they include unusual facial characteristics (broad forehead; deep-set, widely spaced eyes; long, straight nose; and an underdeveloped mandible). There may also be
Biliary atresia is a condition that occurs in infants and is characterized by the absence of bile ducts in the liver, leading to liver damage and complications. The condition can be divided into two major types: embryonic (BA) and perinatal (BA). Embryonic BA typically occurs before 11 weeks of gestation, while perinatal BA occurs after the initiation of bile flow at approximately 11-13 weeks of gestation. Secondary hepatocyte and intrahepatic bile duct injury ensue either as a result of cholestatic injury or as targets for the immune (autoimmune?) response that develops. The end result is intrahepatic cholestasis and portal tract fibrosis, culminating in biliary cirrhosis. Other major factors may be the role played by genetic predisposition to autoimmunity and modifier genes that determine the extent and type of cellular and immune response and the generation of fibrosis.

**Biliary Atresia**
The term *biliary atresia* is imprecise because the anatomy of abnormal bile ducts in affected patients varies markedly. A more appropriate terminology would reflect the pathophysiology, namely noncystic obliterative cholangiopathy. The term *obliterative cholangiopathy* may be divided into 2 major types: cystic and noncystic. The cystic disorder will incorporate the different types of choledochal cysts, while the noncystic form will encompass the 2 types of biliary atresia (fetal and perinatal) in addition to neonatal sclerosing cholangitis.

Patients can have distal segmental bile duct obliteration with patent extrahepatic ducts up to the porta hepatitis. This is a surgically correctable lesion, but it is uncommon. The most common form of biliary atresia, accounting for approximately 85% of the cases, is obliteration of the entire extrahepatic biliary tree at or above the porta hepatitis. This presents a much more difficult problem in surgical management. Most patients with biliary atresia (85-90%) are normal at birth and have a postnatal progressive obliteration of bile ducts; the embryonic or fetal-onset form manifests at birth and is associated with other congenital anomalies (situs inversus, polysplenia, intestinal malrotation, complex congenital heart disease) within the polysplenia spectrum (biliary atresia splenic malformation) (Fig. 356-2; see Chapter 431.11). The postnatal onset may be an immune- or infection-mediated process.

Biliary atresia has been detected in 1 in 10,000-15,000 live births. Biliary atresia is more common in East Asian countries; patients may be born term or preterm. Screening for biliary atresia in infants after birth is not universal, but in high-risk locations, stool color cards that help detect acholic stools have been used with some success. In addition, any infant with new onset or persistent jaundice beyond 8 wk of life should be screened with a total and direct reacting bilirubin level to detect cholestasis.

**Differentiation of Idiopathic Neonatal Hepatitis from Biliary Atresia**
It may be difficult to clearly differentiate infants with biliary atresia, who require surgical correction, from those with intrahepatic disease...
(neonatal hepatitis) and patent bile ducts. No single biochemical test or imaging procedure is entirely satisfactory. Diagnostic schemas incorporate clinical, historical, biochemical, and radiologic features.

Idiopathic neonatal hepatitis has a familial incidence of approximately 20%, whereas biliary atresia is unlikely to recur within the same family. A few infants with fetal onset of biliary atresia have an increased incidence of other abnormalities, such as the polysplenia syndrome with abdominal heterotaxia, malrotation, levocardia, and intraabdominal vascular anomalies. Neonatal hepatitis appears to be more common in infants who are premature or small for gestational age. Persistently acholic stools suggest biliary obstruction (biliary atresia), but patients with severe idiopathic neonatal hepatitis can have a transient severe impairment of bile excretion. Consistently pigmented stools rule against biliary atresia. The finding of bile-stained fluid on duodenal intubation also excludes biliary atresia. Palpation of the liver might find an abnormal size or consistency in patients with biliary atresia; this is less common with idiopathic neonatal hepatitis.

Abdominal ultrasound is a helpful diagnostic tool in evaluating neonatal cholestasis because it identifies choledocholithiasis, perforation of the bile duct, or other structural abnormalities of the biliary tree such as a choledochal cyst. In patients with biliary atresia, ultrasound can detect associated anomalies such as abdominal polysplenia and vascular malformations. The gallbladder either is not visualized or is a microgallbladder in patients with biliary atresia. Children with intrahepatic cholestasis caused by idiopathic neonatal hepatitis, cystic fibrosis, or total parenteral nutrition can have similar ultrasonographic findings. Ultrasonographic triangular cord sign, which represents a cone-shaped fibrotic mass cranial to the bifurcation of the portal vein, may be seen in patients with biliary atresia (Figs. 356-3 and 356-4). The echogenic density, which represents the fibrous remnants at the porta hepatitis of biliary atresia cases at surgery, may be a helpful diagnostic tool in evaluating patients with neonatal cholestasis.

Hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid derivatives is a sensitive but not specific test for biliary atresia. It fails to identify other structural abnormalities of the biliary tree or vascular anomalies. The lack of the specificity of the test and the need to wait for 5 days makes this procedure less practical and of limited usefulness in the evaluation of children with suspected biliary atresia.

Percutaneous liver biopsy is the most valuable procedure in the evaluation of neonatal hepatobiliary diseases and provides the most reliable discriminatory evidence. Biliary atresia is characterized by bile ductular proliferation, the presence of bile plugs, and portal or peribiliary edema and fibrosis, with the basic hepatic lobular architecture intact. In neonatal hepatitis, there is severe, diffuse hepatocellular disease, with distortion of lobular architecture, marked infiltration with inflammatory cells, and focal hepatocellular necrosis; the bile ductules show little alteration. Giant cell transformation is found in infants with either condition and has no diagnostic specificity.

The histologic changes seen in patients with idiopathic neonatal hepatitis can occur in other diseases, including α1-antitrypsin deficiency, galactosemia, and various forms of intrahepatic cholestasis. Although paucity of intrahepatic bile ductules may be detected on liver biopsy even in the 1st few wk of life, later biopsies in such patients reveal a more characteristic pattern.

Management of Patients with Suspected Biliary Atresia

All patients with suspected biliary atresia should undergo exploratory laparotomy and direct cholangiography to determine the presence and site of obstruction. Direct drainage can be accomplished in the few patients with a correctable lesion. When no correctable lesion is found, an examination of frozen sections obtained from the transected porta hepatis can detect the presence of biliary epithelium and determine the size and patency of the residual bile ducts. In some cases, the cholangiogram indicates that the biliary tree is patent but of diminished caliber, suggesting that the cholestasis is not due to biliary tract obliteration but to bile duct paucity or markedly diminished flow in the

Figure 356-3 Surgical findings of biliary atresia. A, Photograph of surgical specimen of obliterated extrahepatic bile ducts shows the fibrous ductal remnant (black arrowheads) in the porta hepatitis, atretic gallbladder (arrow), and fibrous common bile duct (white arrowhead). The fibrous ductal remnant is a triangular cone-shaped mass. B, Schematic represents the anatomic relationship between the fibrous ductal remnant and blood vessels around the porta hepatitis. The triangular, cone-shaped, fibrous ductal remnant (black arrowheads, green) is positioned anterior and slightly superior to the portal vein (long arrow, blue) and the hepatic artery (short arrow, red). (A from Park WH, Choi SO, Lee HJ, et al: A new diagnostic approach to biliary atresia with emphasis on the ultrasonographic triangular cord sign: comparison of ultrasonography, hepatobiliary scintigraphy, and liver needle biopsy in the evaluation of infantile cholestasis, J Pediatr Surg 32:1555–1559, 1997.)

Figure 356-4 Biliary atresia in an 8 wk old male with elevated direct bilirubin. Transverse sonogram shows the triangular cord sign seen as a linear cord of echogenicity (arrowhead) along the right portal vein (RPV). (From Lowe LH: Imaging hepatobiliary disease in children, Semin Roentgenol 43:39–49, 2008, Fig. 1B.)
presence of intrahepatic disease. In these cases, transection of or further dissection into the porta hepatitis should be avoided.

For patients in whom no correctable lesion is found, the hepatoporo-
toenterostomy (Kasai) procedure should be performed. The rationale for this operation is that minute bile duct remnants, representing residual channels, may be present in the fibrous tissue of the porta hepatitis; such channels may be in direct continuity with the intrahepatic ductule system. In such cases, transection of the porta hepatitis with anastomosis of bowel to the proximal surface of the transection might allow bile drainage. If flow is not rapidly established in the 1st mo of life, progressive obliteration and cirrhosis ensues. If microscopic channels of patency > 150 μm in diameter are found, postoperative establishment of bile flow is likely. The success rate for establishing good bile flow after the Kasai operation is much higher (90%) if performed before 8 wk of life. Therefore, early referral and prompt evaluation of infants with suspected biliary atresia is important.

Some patients with biliary atresia, even of the “noncorrectable” type, derive long-term benefits from interventions such as the Kasai procedure. In most, a degree of hepatic dysfunction persists. Patients with biliary atresia usually have persistent inflammation of the intrahepatic biliary tree, which suggests that biliary atresia reflects a dynamic process involving the entire hepatobiliary system. This might account for the ultimate development of complications such as portal hypertension. The short-term benefit of hepatoporoenterostomy is decompression and drainage sufficient to forestall the onset of cirrhosis and sustain growth until a successful liver transplantation can be done.

**MANAGEMENT OF CHRONIC CHOLESTASIS**

With any form of neonatal cholestasis, whether the primary disease is idiopathic neonatal hepatitis, intrahepatic cholestasis, or biliary atresia, affected patients are at increased risk for progression and complications of chronic cholestasis. These reflect various degrees of residual hepatic functional capacity and are due directly or indirectly to diminished bile flow. Any substance normally excreted into bile is retained in the liver, with subsequent accumulation in tissue and in serum. Involved substances include bile acids, bilirubin, cholesterol, and trace elements. Decreased delivery of bile acids to the proximal intestine leads to inadequate digestion and absorption of dietary long-chain triglycerides and fat-soluble vitamins. Impairment of hepatic metabolic function can alter hormonal balance and utilization of nutrients. Progressive liver damage can lead to biliary cirrhosis, portal hypertension, and liver failure.

Treatment of such patients is empirical, and is guided by careful monitoring (Table 356-5). No therapy is known to be effective in halting the progression of cholestasis or in preventing further hepato-cellular damage and cirrhosis.

Growth failure is a major concern and is related in part to malab-soption and malnutrition resulting from ineffective digestion and absorption of dietary fat. Use of a medium-chain triglyceride-containing formula can improve caloric balance.

With chronic cholestasis and prolonged survival, children with hepatobiliary disease can experience deficiencies of the fat-soluble vitamins (A, D, E, K). Inadequate absorption of fat and fat-soluble vitamins may be exacerbated by administration of the bile acid binder cholestyramine. Metabolic bone disease is common.

Serum vitamin A concentration can usually be maintained at normal levels in patients who have chronic cholestasis and who receive oral supplementation of vitamin A esters. It is essential to monitor the vitamin A status in such patients.

A **degenerative neuromuscular syndrome** was found in patients with chronic cholestasis, caused by fat-soluble vitamin malabsorption and vitamin E deficiency; affected children experience progressive areflexia, cerebellar ataxia, ophthalmoplegia, and decreased vibratory sensation. Specific morphologic lesions were found in the central nervous system, peripheral nerves, and muscles. These lesions are preventable and are not commonly seen today; they were potentially reversible in children younger than 3–4 yr of age. Affected children have low serum vitamin E concentrations, increased hydrogen peroxide hemolysis, and low ratios of serum vitamin E to total serum lipids (<0.6 mg/g for children younger than 12 yr and <0.8 mg/g for older patients). Vitamin E deficiency may be prevented by oral administration of large doses (up to 1,000 IU/day); patients unable to absorb sufficient quantities may require administration of d-α-tocopheryl polyethylene glycol 1,000 succinate orally. Serum levels may be monitored as a guide to efficacy.

Pruritus is a particularly troublesome complication of chronic cholestasis, often with the appearance of xanthomas. Both features seem to be related to the accumulation of cholesterol and bile acids in serum and in tissues. Elimination of these retained compounds is difficult when bile ducts are obstructed, but if there is any degree of bile duct patency, administration of ursodeoxycholic acid can increase bile flow or interrupt the enterohepatic circulation of bile acids and thus decrease the xanthomas and ameliorate the pruritus (see Table 356-5). Ursodeoxycholic acid therapy can also lower serum cholesterol levels. The recommended initial dose is 15 mg/kg/24 hr.

TPGS, d-tocopherol polyethylene glycol 1,000 succinate.
Partial external biliary diversion is efficacious in managing pruritus refractory to medical therapy and provides a favorable outcome in a select group of patients with chronic cholestasis who have not yet developed cirrhosis. The surgical technique involves resecting a segment of intestine to be used as a biliary conduit. One end of the conduit is attached to the gallbladder and the other end is brought out to the skin, forming a stoma. The main drawback of the procedure is the need to use an ostomy bag.

Progressive fibrosis and cirrhosis lead to the development of portal hypertension and consequently to ascites and variceal hemorrhage. The presence of ascites is a risk factor for the development of spontaneous bacterial peritonitis. The first step in the management of patients with ascites is to rule out spontaneous bacterial peritonitis and restrict sodium intake to 0.5 g (~1-2 mEq/kg/24 hr). There is no need for fluid restriction in patients with adequate renal output. Should this be ineffective, diuretics may be helpful. The diuretic of choice is spironolactone (3-5 mg/kg/24 hr in 4 doses). If spironolactone alone does not control ascites, the addition of another diuretic such as thiazide or furosemide may be beneficial. Patients with ascites but without peripheral edema are at risk for reduced plasma volume and decreased urine output during diuretic therapy. Tense ascites alters renal blood flow and systemic hemodynamics. Paracentesis and intravenous albumin infusion can improve hemodynamics, renal perfusion, and symptoms. Follow-up includes dietary counseling and monitoring of serum and urinary electrolyte concentrations.

In patients with portal hypertension, variceal hemorrhage and the development of hypersplenism are common. It is important to ascertain the cause of bleeding because episodes of gastrointestinal hemorrhage in patients who have chronic liver disease may be from gastritis or peptic ulcer disease. Because the management of these various complications differs, differentiation, perhaps via endoscopy, is necessary before treatment is initiated. If the patient is volume depleted, blood transfusion should be carefully administered, avoiding overttransfusion, which can precipitate further bleeding. Balloon tamponade is not recommended in children because it can be associated with significant complications. Sclerotherapy or endoscopic variceal ligation may be useful palliative measures in the management of bleeding varices and may be superior to surgical alternatives.

For patients with advanced liver disease, hepatic transplantation has a success rate >85%. If the operation is technically feasible, it will prolong life and might correct the metabolic error in diseases such as α1-antitrypsin deficiency, tyrosinemia, and Wilson disease. Success depends on adequate intraoperative, preoperative, and postoperative care, and on cautious use of immunosuppressive agents. Scarcity of donors of small livers severely limits the application of liver transplantation for infants and children. The use of reduced-size transplants and living donors increases the ability to treat small children successfully.

PROGNOSIS

For patients with idiopathic neonatal hepatitis, the variable prognosis might reflect the heterogeneity of the disease. In sporadic cases, 60-70% recover with no evidence of hepatic structural or functional impairment. Approximately 5-10% have persistent fibrosis or inflammation, and a smaller percentage have more severe liver disease, such as cirrhosis. Infants usually die early in the course of the illness, owing to hemorrhage or sepsis. Of infants with idiopathic neonatal hepatitis of the familial variety, only 20-30% recover; 10-15% acquire chronic liver disease with cirrhosis. Liver transplantation may be required.

**Bibliography is available at Expert Consult.**

### 356.2 Cholestasis in the Older Child

**H. Hesham Abdel-Kader Hassan and William F. Balistreri**

Cholestasis with onset after the neonatal period is most often caused by acute viral hepatitis or exposure to hepatotoxic drugs. However, many of the conditions causing neonatal cholestasis can also cause chronic cholestasis in older patients. Consequently, older children and adolescents with conjugated hyperbilirubinemia should be evaluated for acute and chronic viral hepatitis, α1-antitrypsin deficiency, Wilson disease, liver disease associated with inflammatory bowel disease, autoimmune hepatitis, drug-induced liver injury, and the syndromes of intrahepatic cholestasis. Other causes include obstruction caused by cholelithiasis, abdominal tumors, enlarged lymph nodes, or hepatic inflammation resulting from drug ingestion. Management of cholestasis in the older child is similar to that proposed for neonatal cholestasis (see Table 356-5).

Metabolic liver diseases in children, although individually rare, altogether represent a significant cause of morbidity and mortality. The liver has a central role in synthetic, degradative, and regulatory pathways involving carbohydrate, protein, lipid, trace element, and vitamin metabolism. Inborn errors of metabolism result in metabolic abnormalities, specific enzyme deficiencies or defects, and disorders of protein transport that can have primary or secondary effects on the liver (Table 357-1). Liver disease can arise when absence of an enzyme produces a block in a metabolic pathway, when unmetabolized substrate accumulates proximal to a block, when deficiency of an essential substance produced distal to an aberrant chemical reaction develops, or when synthesis of an abnormal metabolite occurs. The spectrum of pathologic changes includes hepatocyte injury, with subsequent failure of other metabolic functions, often eventuating in cirrhosis, liver tumors, or both; storage of lipid, glycogen, or other products manifested as hepatomegaly, often with complications specific to deranged metabolism (hypoglycemia with glycogen storage disease); and absence of structural change despite profound metabolic effects, as with urea cycle defects. Clinical manifestations of metabolic diseases of the liver mimic infections, intoxications, and hematologic and immunologic diseases (Table 357-2). Many metabolic diseases are detected in expanded newborn metabolic screening programs (see Chapter 84). Clues are provided by family history of a similar illness or by the observation that the onset of symptoms is closely associated with a change in dietary habits; in patients with hereditary fructose intolerance, symptoms follow ingestion of fructose (sucrose). Clinical and laboratory evidence often guides the evaluation. Liver biopsy offers morphologic study and permits enzyme assays, as well as quantitative and qualitative assays of various other constituents (e.g., hepatic copper content in Wilson disease). Genetic/molecular diagnostic approaches are also available. Such studies require cooperation of experienced laboratories and careful attention to collection and handling of specimens. Treatment depends on the specific type of defect and although relatively uncommon, altogether metabolic diseases of the liver account for up to 10% of the indications for liver transplantation in children, a number that may be underestimated given the acute nature of some of these conditions, precluding complete diagnostic investigation prior to transplantation.
### 357.1 Inherited Deficient Conjugation of Bilirubin (Familial Nonhemolytic Unconjugated Hyperbilirubinemia)

**Alexandra N. Menchise and William F. Balistreri**

Bilirubin is the metabolic end product of heme. Before excretion into bile, it is first glucuronidated by the enzyme bilirubin-uridine diphosphoglucuronate glucuronosyltransferase (UDPGT). UDPGT activity is deficient or altered in 3 genetically and functionally distinct disorders (Crigler-Najjar [CN] syndromes type I and II and Gilbert syndrome), producing congenital nonobstructive, nonhemolytic, unconjugated hyperbilirubinemia. UGT1A1 is the primary UDPGT isoform needed for bilirubin glucuronidation, and complete absence of UGT1A1 activity causes CN type I. CN type II is caused by decreased UGT1A1 activity.

**Gilbert syndrome** is caused by a common polymorphism, a TA insertion in the promoter region of UGT1A1 that leads to decreased binding of the TATA binding protein and decreases normal gene activity but only to approximately 30%. Snapback primer genotyping can distinguish all UGT1A1 promoter genotypes. Unlike the CN syndromes, Gilbert syndrome usually occurs after puberty; it is not associated with chronic liver disease and no treatment is required. However, it is more common, affecting up to 5-10% of the white population with total serum bilirubin concentrations that fluctuate from 1-6 mg/dL. Because UGT1A1 is involved in glucuronidation of multiple substrates other than bilirubin (e.g., pharmaceutical drugs, endogenous hormones, environmental toxins, and aromatic hydrocarbons) and glucuronidation leads to inactivation of these substrates, mutations in the UGT1A1 gene are implicated in cancer risk and the predisposition to drug toxicity specifically in cancer chemotherapy and episodes of jaundice when exposed to the agents.

**Crigler-Najjar Syndrome Type I (GLUCURONYL TRANSFERASE DEFICIENCY)**

CN type I is rare and inherited as an autosomal recessive trait and is usually secondary to mutations that cause a premature stop codon or frameshift mutation and thereby abolish UGT1A1 activity. As many as 59 mutations have been identified to date. Parents of affected children have partial defects in conjugation as determined by hepatic specific enzyme assay or by measurement of glucuronide formation; their serum unconjugated bilirubin concentrations are normal.

**Clinical Manifestations**

Severe unconjugated hyperbilirubinemia develops in homozygous affected infants in the 1st 3 days of life, and without treatment, serum unconjugated bilirubin concentrations of 25-35 mg/dL are reached in the 1st mo. Kernicterus, an almost universal complication of this disorder, is usually first noted in the early neonatal period; some treated infants have survived childhood without clinical sequelae. Stools are

pale yellow. Persistence of unconjugated hyperbilirubinemia at levels >20 mg/dL for at least 1 wk of life in the absence of hemolysis should suggest the syndrome.

**Diagnosis**
The diagnosis of CN type I is based on the early age of onset and the extreme level of bilirubin elevation in the absence of hemolysis. In the bile, bilirubin concentration is <10 mg/dL compared with normal concentrations of 50-100 mg/dL; there is no bilirubin glucuronide. Definitive diagnosis is established by measuring hepatic glucuronyl transferase activity in a liver specimen obtained by a closed biopsy; open biopsy should be avoided because surgery and anesthesia can precipitate kernicterus. DNA diagnosis is also available and may be preferable. Identification of the heterozygous state in parents also strongly suggests the diagnosis. The differential diagnosis of unconjugated hyperbilirubinemia is discussed in Chapter 102.3.

**Treatment**
The serum unconjugated bilirubin concentration should be kept to <20 mg/dL for at least the 1st 2-4 wk of life; in low birthweight infants, the levels should be kept lower. This usually requires repeated exchange transfusions and phototherapy in the immediate neonatal period. Oral calcium phosphate supplementation renders phototherapy more effective as it forms complexes with bilirubin in the gut. Phenobarbital therapy, through CYP450 enzyme induction, should be considered to determine responsiveness and differentiation between types I and II. In patients with CN type I there is no response to phenobarbital treatment.

The risk of kernicterus persists into adult life, although the serum bilirubin levels required to produce brain injury beyond the neonatal period are considerably higher (usually >35 mg/dL). Therefore, phototherapy is generally continued through the early years of life. In older infants and children, phototherapy is used mainly during sleep so as not to interfere with normal activities. Despite the administration of increasing intensities of light for longer periods, the serum bilirubin response to phototherapy decreases with age. Additional adjuvant therapy using agents that bind photobilirubin products such as cholestyramine or agar can also be used to interfere with the enterohepatic recirculation of bilirubin.

Prompt treatment of intercurrent infections, febrile episodes, and other types of illness might help prevent the later development of kernicterus, which can occur at bilirubin levels of 45-55 mg/dL. All patients with CN type I have eventually experienced severe kernicterus by young adulthood.

Orthotopic liver transplantation cures the disease and has been successful in a small number of patients; isolated hepatocyte transplantation has been reported as bridge therapy to liver transplantation, with most, but not all patients eventually requiring orthotopic transplantation. Other therapeutic modalities have included plasmapheresis and limitation of bilirubin production. The latter option, inhibiting bilirubin generation, is possible via inhibition of heme oxygenase using metalloporphyrin therapy.

**CRIGLER-NAJJAR SYNDROME TYPE II (PARTIAL GLUCURONYL TRANSFERASE DEFICIENCY)**
Like CN type I, CN type II is an autosomal recessive disease; it is caused by homozygous missense mutations in UGT1A1, resulting in reduced (partial) enzymatic activity. More than 45 mutations have been identified to date. Type II disease can be distinguished from type I by the marked decline in serum bilirubin level that occurs in type II disease after treatment with phenobarbital secondary to an inducible phenobarbital response element on the UGT1A1 promoter.

**Clinical Manifestations**
When this disorder appears in the neonatal period, unconjugated hyperbilirubinemia usually occurs in the 1st 3 days of life; serum bilirubin concentrations can be in a range compatible with physiologic jaundice or can be at pathologic levels. The concentrations characteristically remain elevated into and after the 3rd wk of life, persisting in a range of 1.5-22 mg/dL; concentrations in the lower part of this range can create uncertainty about whether chronic hyperbilirubinemia is present. Development of kernicterus is unusual, and the infants are without clinical signs or symptoms of disease. There is no evidence of hemolysis. Liver enzymes and synthetic function tests are typically normal.

**Diagnosis**
Concentration of bilirubin in bile is nearly normal in patients with CN type II. Jaundiced infants and young children with type II syndrome respond readily to 5 mg/kg/24 hr of oral phenobarbital, with a decrease in serum bilirubin concentration to 2-3 mg/dL in 7-10 days.

**Treatment**
Long-term reduction in serum bilirubin levels can be achieved with continued administration of phenobarbital at 5 mg/kg/24 hr. The cosmetic and psychosocial benefit should be weighed against the risks of an effective dose of the drug because there is a small long-term risk of kernicterus even in the absence of hemolytic disease. Orlistat, an irreversible inhibitor of intestinal lipase, increases fecal fat excretion and decreases plasma unconjugated bilirubin concentrations (~10%) in patients with CN types I and II.

**INHERITED CONJUGATED HYPERBILIRUBINEMIA**
Conjugated hyperbilirubinemia can be caused by a small number of rare autosomal recessive conditions characterized by mild jaundice. The transfer of bilirubin and other organic anions from the liver cell to bile is defective. Chronic mild conjugated hyperbilirubinemia is usually detected during adolescence or early adulthood but can occur as early as the second year of life. The results of routine liver function tests are normal. Jaundice can be exacerbated by infection, pregnancy, oral contraceptives, alcohol consumption, and surgery. There is usually no morbidity and life expectancy is normal, but these disorders can initially present difficult problems in the differential diagnosis of more serious diseases.

**DUBIN-JOHNSON SYNDROME**
Dubin-Johnson syndrome is an autosomal recessive inherited defect with variable penetrance in hepatocyte secretion of bilirubin glucuronide. The defect in hepatic excretory function is not limited to conjugated bilirubin excretion but also involves several organic anions normally excreted from the liver cell into bile. Absent function of multiple drug-resistant protein 2 (MRP2), an adenosine triphosphate–dependent canalicular transporter, is the responsible defect. More than 10 different mutations, including compound heterozygous mutation in the CMOAT gene, have been identified and either affect localization of MRP2 with resultant increased degradation or impair MRP2 transport activity in the canalicular membrane. Bile acid excretion and serum bile acid levels are normal. Total urinary coproporphyrin excretion is normal in quantity but coproporphyrin I excretion increases to approximately 80% with a concomitant decrease in coproporphyrin III excretion. Normally, coproporphyrin III is >75% of the total. Cholangiography fails to visualize the biliary tract and x-ray of the gallbladder is also abnormal. Liver histology demonstrates normal architecture, but hepatocytes contain black pigment similar to melanin. Liver function is normal and prognosis is excellent. The most commonly reported symptoms are abdominal pain and fatigue, jaundice, dark urine, and slight enlargement of the liver. Jaundice fluctuates in intensity and is aggravated by intercurrent disease.

**Rotor Syndrome**
Patients with Rotor syndrome have an additional deficiency in organic anion uptake. Biallelic inactivating mutations in the linked genes **SLCO1B1** and **SLCO1B3** result in functional deficiencies of both
protein products (OATP1B1 and OATP1B, respectively) and are reported to cause Rotor syndrome. Importantly, these mutations may confer significant drug toxicity risk. Unlike Dubin-Johnson syndrome, total urinary coproporphyrin excretion is elevated, with a relative increase in the amount of the coproporphyrin I isomer. The gallbladder is normal by roentgenography, and liver cells contain no black pigment. In Dubin-Johnson and Rotor syndromes, sulfobromophthalein excretion is often abnormal.

357.2 Wilson Disease
Alexandra N. Menchise and William F. Balistreri

Wilson disease (hepatolenticular degeneration) is an autosomal recessive disorder that can be associated with degenerative changes in the brain, liver disease, and Kayser-Fleischer rings in the cornea (Fig. 357-1). The incidence is 1 in 55,000 births in the United States and 1 in 30,000 to 1 in 50,000 births worldwide. It is progressive and potentially fatal if untreated; specific effective treatment is available. Rapid diagnostic investigation of the possibility of Wilson disease in a patient presenting with any form of liver disease, particularly if older than 5 yr of age, not only facilitates early institution of management of Wilson disease and related genetic counseling but also allows appropriate treatment of non-Wilsonian liver disease once copper toxicosis is ruled out.

PATHOGENESIS

The abnormal gene for Wilson disease is localized to the long arm of chromosome 13 (13q14.3). The Wilson disease gene encodes a copper transporting P-type adenosine triphosphatase (ATPase), ATP7B, which is mainly but not exclusively expressed in hepatocytes and is critical for biliary copper excretion and for copper incorporation into ceruloplasmin. Absence or malfunction of ATP7B results in decreased biliary copper excretion and diffuse accumulation of copper in the cytosol of hepatocytes. With time, liver cells become overloaded and copper is redistributed to other tissues, including the brain and kidneys, causing toxicity, primarily as a potent inhibitor of enzymatic processes. Ionic copper inhibits pyruvate oxidase in brain and ATPase in membranes, leading to decreased adenosine triphosphate-phosphocreatine and potassium content of tissue.

More than 500 mutations in the gene have been identified from which 380 have a confirmed role in the pathogenesis of the disease, making diagnosis by DNA mutational analysis a difficult task unless a proband mutation is known. Most patients are compound heterozygotes. Mutations that completely knock out gene function are associated with an onset of disease symptoms as early as 2-3 yr of age, when Wilson disease might not typically be considered in the differential diagnosis. Milder mutations can be associated with neurologic symptoms or liver disease as late as 80 yr of age.

CLINICAL MANIFESTATIONS

Forms of Wilsonian hepatic disease include asymptomatic hepatomegaly (with or without splenomegaly), subacute or chronic hepatitis, and acute hepatic failure (with or without hemolytic anemia). Cryptogenic cirrhosis, portal hypertension, ascites, edema, variceal bleeding, or other effects of hepatic dysfunction (delayed puberty, amenorrhea, coagulation defects) can be manifestations of Wilson disease.

Disease presentations are variable, with a tendency to familial patterns. The younger the patient, the more likely hepatic involvement will be the predominant manifestation. Girls are 3 times more likely than boys to present with acute hepatic failure. Clinically evident liver disease may precede neurologic manifestations by as much as 10 yr. After 20 yr of age, neurologic symptoms predominate.

Neurologic disorders can develop insidiously or precipitously, with intention tremor, dysarthria, rigid dystonia, Parkinsonism, choreiform movements, lack of motor coordination, deterioration in school performance, or behavioral changes. Kayser-Fleischer rings are absent in young patients with hepatic Wilson disease up to 50% of the time but are present in 95% of patients with neurologic symptoms and somewhat over half of those without neurologic symptoms. Psychiatric manifestations include depression, personality changes, anxiety, or psychosis.

Coombs-negative hemolytic anemia may be an initial manifestation, possibly related to the release of large amounts of copper from damaged hepatocytes; this form of Wilson disease is usually fatal without transplantation. During hemolytic episodes, urinary copper excretion and serum copper levels (not ceruloplasmin bound) are markedly elevated. Manifestations of renal Fanconi syndrome and progressive renal failure with alterations in tubular transport of amino acids, glucose, and uric acid may be present. Unusual manifestations include arthritis, pancreatitis, nephrolithiasis, infertility or recurrent miscarriages, cardiomyopathy, and endocrinopathies (hypoparathyroidism).

PATHOLOGY

All grades of hepatic injury occur in patients with Wilson disease with steatosis, hepatocellular ballooning and degeneration, glycogen granules, minimal inflammation, and enlarged Kupffer cells being most common. The earliest histologic feature is often mild steatosis and this may be misdiagnosed as nonalcoholic fatty liver disease or nonalcoholic steatohepatitis. Additionally, the lesion may be indistinguishable from that of autoimmune hepatitis. With progressive parenchymal damage, fibrosis and cirrhosis develop. Ultrastructural changes primarily involve the mitochondria and include increased density of the matrix material, inclusions of lipid and granular material, and increased intracisternal space with dilution of the tips of the cristae.

DIAGNOSIS

Wilson disease should be considered in children and teenagers with unexplained acute or chronic liver disease, neurologic symptoms of unknown cause, acute hemolysis, psychiatric illnesses, behavioral changes, Fanconi syndrome, or unexplained bone (osteoporosis, fractures) or muscle disease (myopathy, arthralgia). The clinical suspicion is confirmed by study of indices of copper metabolism.

Most patients with Wilson disease have decreased ceruloplasmin levels (<20 mg/dL). The failure of copper to be incorporated into ceruloplasmin leads to a plasma protein with a shorter half-life and, therefore, a reduced steady-state concentration of ceruloplasmin in the circulation. Caution should be used in interpreting serum ceruloplasmin levels, because they may be elevated in acute inflammation and in states of elevated estrogen such as pregnancy, estrogen supplementation, or oral contraceptive use and may be low in autoimmune hepatitis, celiac disease, familial aceruloplasminemia or in heterozygous carriers of ATP7B mutations who do not show copper overload disease.
Bibliography

The serum “free” copper level may be elevated in early Wilson disease (>1.6 µmol/L), and urinary copper excretion (usually <40 µg/day) is increased to >100 µg/day and often up to 1,000 µg or more per day (typical findings in Wilson disease: urine copper excretion >1.6 µmol/24 hr, >0.64 µmol/24 hr in children). In equivocal cases, the response of urinary copper output to chelation may be of diagnostic help. During the 24 hr urine collection patients are given two 500 mg oral doses of d-penicillamine 12 hr apart; affected patients excrete >1,600 µg/24 hr.

Demonstration of Kayser-Fleischer rings, which might not be present in younger children, requires a slit-lamp examination by an ophthalmologist. After adequate treatment, Kayser-Fleischer rings resolve.

Liver biopsy is of value for determining the extent and severity of liver disease and for measuring the hepatic copper content (normally <10 µg/g dry weight) but is only required if clinical signs and noninvasive tests do not allow a final diagnosis or if another liver disorder is suspected. Hepatic copper accumulation is the hallmark of Wilson disease and measurement of hepatic parenchymal copper concentration is the method of choice for diagnosis. In Wilson disease, hepatic copper content usually exceeds 250 µg/g dry weight (>4 µmol/g dry weight is the best biochemical evidence for Wilson disease but lowering the threshold to 1.2 µmol/g dry weight improves sensitivity without significantly affecting specificity). In healthy heterozygotes, levels may be intermediate. In later stages of Wilson disease hepatic copper content can be unreliable because cirrhosis leads to variable hepatic copper distribution and sampling error.

Family members of patients with proven cases require screening for presymptomatic Wilson disease. Such screening should include determination of the ceruloplasmin level and urinary copper excretion. If these results are abnormal or equivocal, liver biopsy should be carried out to determine morphology and hepatic copper content. Genetic screening by either linkage analysis or direct DNA mutation analysis is possible, especially if the mutation for the proband case is known or the patient is from an area where a specific mutation is known (in central and eastern Europe, the H1069Q mutation is present in 50-80% of patients).

**TREATMENT**

A major attempt should be made to restrict dietary copper intake to <1 mg/day. Foods such as liver, shellfish, nuts, and chocolate should be avoided. If the copper content of the drinking water exceeds 0.1 mg/L, it may be necessary to demineralize the water. Once the diagnosis has been made, treatment needs to be lifelong.

The initial treatment in symptomatic patients is the administration of copper-chelating agents, which leads to rapid excretion of excess deposited copper. Chelation therapy is managed with oral administration of d-penicillamine (0.5-2.0 g/day) and urinary copper excretion markedly increases, and with continued administration, urinary copper levels can become normal, with marked improvement in hepatic and neurologic function and the disappearance of Kayser-Fleischer rings.

Approximately 10-50% of patients initially treated with penicillamine for neurologic symptoms have a worsening of their condition. Toxic effects of penicillamine occur in 10-20% and consist of hypersensitivity reactions (i.e., Goochpasture syndrome, systemic lupus erythematosus, polymyositis), interaction with collagen and elastin, deficiency of other elements such as zinc, and aplastic anemia and nephrosis. Because penicillamine is an antimetabolite of vitamin B₆, additional amounts of this vitamin are necessary. For these reasons, triethylene tetramine dihydrochloride is a preferred alternative, and is considered first-line therapy for some patients. Trientine has few known side effects. Ammonium tetrathiomolybdate is another alternative chelating agent under investigation for patients with neurologic disease; initial results suggest that significantly fewer patients experience neurologic deterioration with this drug compared to penicillamine. The initial dose is 120 mg/day (20 mg between meals tid and 20 mg with meals tid). Side effects include anemia, leukopenia, thrombocytopenia, and mild elevations of transaminases. Because of its extensive decoppering effect, ammonium tetrathiomolybdate also has antiangiogenic effects.

Zinc has also been used as adjuvant therapy, maintenance therapy, or primary therapy in presymptomatic patients, owing to its unique ability to impair the gastrointestinal absorption of copper. Zinc acetate is given in adults at a dose of 25-50 mg of elemental zinc 3 times a day, and 25 mg 3 times a day in children older than 5 yr of age. Side effects are mostly limited to gastric irritation but also include reduced leukocyte chemotaxis and elevations in serum lipase and/or amylase. Current guidelines recommend that all symptomatic patients with Wilson disease receive a chelating agent (penicillamine or trientine). Zinc may have a role as a first-line therapy in patients with neurologic disease but exclusive monotherapy with zinc in symptomatic liver disease is controversial and not recommended.

Antioxidants (vitamin E and curcumin) and pharmacologic chaperones (4-phenylbutyrate and curcumin) may have a role as adjunctive treatment but more research is needed.

**PROGNOSIS**

Untreated patients with Wilson disease can die of hepatic, neurologic, renal, or hematologic complications. Medical therapy is rarely effective in those presenting with acute liver failure. The prognosis for patients receiving prompt and continuous penicillamine is variable and depends on the time of initiation of and the individual response to chelation. Liver transplantation should be considered for patients with fulminant liver disease, decompensated cirrhosis, or progressive neurologic disease; the last indication remains controversial. Liver transplantation is curative, with a survival rate of approximately 85-90%. In asymptomatic siblings of affected patients, early institution of chelation or zinc therapy can prevent expression of the disease.

*Bibliography is available at Expert Consult.*

**357.3 Indian Childhood Cirrhosis**

Alexandra N. Menchise and William F. Balistreri

Indian childhood cirrhosis (ICC) is a chronic liver disease of young children unique to the Indian subcontinent. ICC manifests with jaundice, pruritus, lethargy, and hepatosplenomegaly. Untreated ICC has a mortality of 40-50% within 4 wks. Histologically, it is characterized by hepatocyte necrosis, Mallory bodies, intralobular fibrosis, and inflammation.

The etiology has remained elusive; it was once believed that excess copper ingestion in the setting of a genetic susceptibility to copper toxicity was the most likely cause. Epidemiologic data demonstrates that the copper toxicity theory is unlikely. The increased hepatic copper content, usually >700 µg/g dry weight, seen in ICC is only seen in the late stages of disease and is accompanied by even higher levels of zinc, a non-hepatotoxic metal. The copper-contaminated utensils used to feed babies and implicated in excess copper ingestion are found in only 10-15% of all cases. The current hypothesis implicates the postnatal use of local hepatotoxic therapeutic remedies, although the exact causative agent is unknown.

Over the last few decades, as the awareness of the disease has increased, the incidence of ICC has decreased and has even been virtually eliminated in some areas of India although established and non-typical cases are probably being missed because of lack of histologic confirmation and unawareness of the protean manifestations and natural history of this disease. Variants of this syndrome have been named according to the population where it has been described, such as Tyrolean childhood cirrhosis or North American ICC. It has also been reported in the Middle East, West Africa, and North and Central America.

Bibliography

Bibliography
Neonatal iron storage disease (NISD), also known as neonatal hemochromatosis, is a rare form of fulminant liver disease that manifests in the first few days of life. It is unrelated to the familial forms of hereditary hemochromatosis that occur later in life. NISD has a high rate of recurrence in families, with approximately 80% probability that subsequent infants will be affected. NISD is postulated to be a gestational alloimmune disease and has also been classified as congenital alloimmune hepatitis. Alloimmunity develops in the pregnant mother of the affected infant when she is exposed to an unknown fetal hepaticocyte cell surface antigen that she does not recognize as self. Maternal immunoglobulin G to this fetal antigen then crosses the placenta and induces hepatic injury via immune system activation. The defining feature of gestational alloimmune liver disease is complement-mediated hepaticocyte injury, the evidence for which comes from detection of the C5b-9 complex by immunohistochemistry. Additional evidence of a gestational insult is given by the fact that affected infants may be born prematurely or with intrauterine growth restriction. Several infants with NISD also have renal dysgenesis.

Excess non–transferrin-bound iron in gestational alloimmune liver disease may result from fetal liver injury that causes reduced synthesis of key iron regulatory and transport proteins. The pattern of extracellular siderosis appears to be determined by the normal capacity of various tissues to import non–transferrin-bound iron and not export cellular iron. It is now thought that fetal liver injury is the primary event leading to the development of the neonatal hemochromatosis phenotype providing further evidence that this is not a primary iron overload disease.

NISD is a rapidly fatal, progressive illness characterized by hepatomegaly, hypoglycemia, hyprothrombinemia, hypoalbuminemia, hyperferritinemia, and hyperbilirubinemia. The coagulopathy is refractory to therapy with vitamin K. Liver pathology demonstrates severe liver injury with acute and chronic inflammation, fibrosis, and cirrhosis. The diagnosis can be confirmed in the neonate with severe liver injury and extracellular siderosis (biopsy material of buccal mucosal glands is laden with iron) or MRI determination of iron storage in organs such as the pancreas.

The prognosis for affected infants is generally poor, but some patients with NISD have been successfully treated with iron-chelating agents (deferoxamine) combined with aggressive antioxidant therapy. Combining this therapy with double volume exchange transfusion followed by administration of intravenous immunoglobulin (IVIG) has also been shown to remove the injury-causing maternal immunoglobulin G. Liver transplantation should also be an early consideration. Recurrences of NISD may be modified with IVIG administered to the mother once a wk from the 18th wk of gestation until delivery. The largest experience reports 48 women with previous infants with NISD who successfully delivered 52 babies after IVIG treatment. The majority of infants had biochemical evidence of liver disease with elevated serum α1-fetoprotein and ferritin. All infants survived with medical therapy or no therapy.

Bibliography is available at Expert Consult.

357.5 Miscellaneous Metabolic Diseases of the Liver
Alexandra N. Menchise and William F. Balistreri

α1-ANTITRYPSIN DEFICIENCY
A small percentage of patients homozygous for deficiency of the major serum protease inhibitor α1-antitrypsin manifest neonatal cholestasis or later-onset childhood cirrhosis. α1-Antitrypsin deficiency is caused by mutation in the SERPINA1 gene and it is an autosomal recessive disorder. α1-Antitrypsin, a protease inhibitor synthesized by the liver, protects lung alveolar tissues from destruction by neutrophil elastase (see Chapter 393). α1-Antitrypsin is present in more than 20 different codominant alleles, only a few of which are associated with defective protease inhibitors. The most common allele of the protease inhibitor (Pi) system is M, and the normal phenotype is PiMM. The Z allele predisposes to clinical deficiency; patients with liver disease are usually PiZZ homozygotes and have serum α1-antitrypsin levels <2 mg/mL (<10–20% of normal). The incidence of the PiZZ genotype in the white population is estimated at 1 in 2,000–4,000 live births. Compound heterozygotes PiMZ, PiSZ, PiZZ are not a cause of liver disease alone but can act as modifier genes, increasing the risk of progression in other liver disease such as nonalcoholic fatty liver disease and hepatitis C. The null phenotype because of stop codons in the coding exon of the α1-antitrypsin gene or complete deletion of α1-antitrypsin coding exons leads to the complete absence of any protein and causes only lung disease.

Newly formed α1-antitrypsin peptide normally enters the endoplasmic reticulum, where it undergoes enzymatic modification and folding before transport to the plasma membrane, where it is excreted as a 55 kDa glycoprotein. In affected patients with PiZZ, the rate at which the α1-antitrypsin peptide folds is decreased, and this delay allows the formation of polymers that are retained in the endoplasmic reticulum. How the polymers cause liver damage is not completely elucidated, but research indicates that accumulation of abnormally folded protein leads to activation of stress and proinflammatory pathways in the endoplasmic reticulum and hepatocyte programmed cell death. In liver biopsies from patients, polymerized α1-antitrypsin peptides can be seen by electron microscopy and histochemically as periodic acid–Schiff-positive diastase-resistant globules primarily in perilobular hepatocytes, but also in Kupffer cells and biliary epithelial cells. The pattern of neonatal liver injury can be highly variable, and liver biopsies might demonstrate hepatocellular necrosis, inflammatory cell infiltration, bile duct proliferation, periportal fibrosis, or cirrhosis.

In affected patients, the course of liver disease is also highly variable. Prospective studies in Sweden have shown that only 10% of patients develop clinically significant liver disease by their 4th decade. Genetic traits or environmental factors must influence the development of disease in α1-antitrypsin–deficient patients. Infants with liver disease are indistinguishable from other infants with “idiopathic” neonatal hepatitis, of whom they constitute approximately 5–10%. Jaundice, acholic stools, and hepatomegaly are present in the 1st wk of life, but the jaundice usually clears in the 2nd–4th mo. Complete resolution, persistent liver disease, or the development of cirrhosis can follow. Older children can present with asymptomatic hepatomegaly or manifestations of chronic liver disease or cirrhosis, with evidence of portal hypertension. Emphysema is not typically observed in children but an increased risk for developing asthma is reported. Cigarette smoking promotes development of lung disease so children should be counseled on avoidance or smoking cessation as part of their anticipatory guidance. Long-term patients are at risk for hepatocellular carcinoma.

Therapy is supportive; liver transplantation has been curative.

CITRIN DEFICIENCY
Neonatal intrahepatic cholestasis caused by citrin deficiency presents in the 1st few mo of life with manifestations that initially may be indistinguishable from other causes of neonatal cholestasis, especially biliary atresia. Patients may have jaundice, hepatomegaly, liver dysfunction with coagulopathy, fatty liver infiltration, hyperammonemia with or without hypoglycemia. Presymptomatic patients may be identified from the newborn metabolic screen with hypergalactosemia, hypermethionemia, and hyperphenylalanemia, not all patients are identified by newborn screening.

Neonatal intrahepatic cholestasis caused by citrin deficiency is caused by a mutation in the SLC25A13 gene, which encodes citrin, a mitochondrial carrier protein (calcium binding aspartate-glutamate carrier) and is involved in the urea cycle, gluconeogenesis and glycolysis. The mutation is most common among East Asian populations.

Affected infants have hypergalactosemia, elevated bile acids, vitamin K–dependent coagulopathy, and elevated levels of citrulline and methionine. Treatment includes that for neonatal cholestasis and in many patients but more severely affected patients may develop progressive hepatic failure requiring liver transplantation in the 1st yr of life.

Bibliography
Viral Hepatitis

M. Kyle Jensen and William F. Balistreri

Viral hepatitis continues to be a major health problem in both developing and developed countries. This disorder is caused by at least 5 pathogenic hepatotropic viruses recognized to date: hepatitis A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV) viruses (Table 358-1). Many other viruses (and diseases) can cause hepatitis, usually as 1 component of a multisystem disease. These include herpes simplex virus, cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, HIV, rubella, adenoviruses, enteroviruses, parvovirus B19, and arboviruses (Table 358-2).

The hepatotropic viruses are a heterogeneous group of infectious agents that cause similar acute clinical illness. In most pediatric patients, the acute phase causes no or mild clinical disease. Morbidity is related to rare cases of acute liver failure (ALF) in susceptible patients, and to the chronic disease state and attendant complications that 3 of these viruses (hepatitides B, C, and D) can cause.

**ISSUES COMMON TO ALL FORMS OF VIRAL HEPATITIS**

**Differential Diagnosis**

Often what brings the patient with hepatitis to medical attention is clinical icterus, with yellow skin and/or mucous membranes. The liver is usually enlarged and tender to palpation and percussion. Splenomegaly and lymphadenopathy may be present. Extrahepatic symptoms (rashes, arthritis) are more readily seen in HBV and HCV infections. Clinical signs of altered sensorium or hyperreflexia should be carefully sought, because they mark the onset of encephalopathy and ALF.

The differential diagnosis varies with age of presentation.

In the newborn period, infection is a common cause of conjugated hyperbilirubinemia; the infectious cause is either a bacterial agent (e.g., *Escherichia coli*, *Listeria*, *syphilis*) or a nonhepatotropic virus (e.g., herpes simplex virus, enteroviruses, cytomegalovirus). Metabolic (α1-antitrypsin deficiency, cystic fibrosis, tyrosinemia), and anatomic causes (biliary atresia, choledochal cysts) and inherited forms of intrahepatic cholestasis should always be excluded.

In later childhood, extrahepatic obstruction (gallstones, primary sclerosing cholangitis, pancreatic pathology), inflammatory conditions (autoimmune hepatitis, juvenile rheumatoid arthritis, Kawasaki disease), immune dysregulation (hemophagocytic lymphohistiocytosis), infiltrative disorders (malignancies), toxins and medications, metabolic disorders (Wilson disease, cystic fibrosis), and infection (Epstein-Barr virus, varicella, malaria, leptospirosis, *syphilis*) should be ruled out.

**Pathogenesis**

The acute response of the liver to hepatotropic viruses involves a direct cytopathic and an immune-mediated injury. The entire liver is involved. Necrosis is usually most marked in the centrilobular areas. An acute mixed inflammatory infiltrate predominates in the portal areas but also affects the lobules. The lobular architecture remains intact, although balloon degeneration and necrosis of single or groups of parenchymal cells commonly occurs. Fatty change is rare except with HCV infection. Bile duct proliferation but not bile duct damage is common. Diffuse Kupffer cell hyperplasia is noticeable in the sinusoids. Neonates often respond to hepatic injury by forming giant cells.

In fulminant hepatitis, parenchymal collapse occurs on the just-described background.

With recovery, the liver morphology returns to normal within 3 mo of the acute infection. If chronic hepatitis develops, the inflammatory infiltrate settles in the periportal areas and often leads to progressive scarring. Both of these hallmarks of chronic hepatitis are seen in cases of HBV and HCV.

**Common Biochemical Profiles in the Acute Infectious Phase**

Acute liver injury caused by the hepatotropic viruses manifests in 3 main functional liver biochemical profiles. These serve as an important guide to supportive care and monitoring in the acute phase of the infection for all viruses.

As a reflection of cytopathic injury to the hepatocytes, there is a rise in serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The magnitude of enzyme elevation does not correlate with the extent of hepatocellular necrosis and has little prognostic value. There is usually slow improvement over several weeks, but AST and ALT levels lag behind the serum bilirubin level, which tends to normalize first. Rapidly falling aminotransferase levels can predict a poor outcome, particularly if their decline occurs in conjunction with a rising bilirubin level and a prolonged prothrombin time; this combination of findings usually indicates that massive hepatic injury has occurred.

**Cholestasis**, defined by elevated serum conjugated bilirubin levels, results from abnormal bile flow at the canicular and cellular level as a result of hepatocyte damage and inflammatory mediators. Elevation of serum alkaline phosphatase, 5′-nucleotidase, γ-glutamyl transpeptidase, and urobiligenon mark cholestasis. Improvement tends to parallel the acute hepatitis phase. Absence of cholestatic markers

does not rule out progression to chronicity in HCV or HBV infections.

Altered synthetic function is the most important marker of liver injury. Monitoring of synthetic function should be the main focus in clinical follow-up to define the severity of the disease. In the acute phase, the degree of liver synthetic dysfunction guides treatment and helps to establish intervention criteria. Abnormal liver synthetic function is a marker of liver failure and is an indication for prompt referral to a transplant center. Serial assessment is necessary because liver dysfunction does not progress linearly. Synthetic dysfunction is reflected by a combination of abnormal protein synthesis (prolonged prothrombin time, high international normalized ratio, low serum albumin levels), metabolic disturbances (hypoglycemia, lactic acidosis, hyperammonemia), poor clearance of medications dependent on liver function, and altered sensorium with increased deep tendon reflexes (hepatic encephalopathy).

**HEPATITIS A**

HAV infection is the most prevalent hepatotropic virus. This virus is also responsible for most forms of acute and benign hepatitis; although fulminant hepatic failure can occur, it is rare (<1% of cases in the United States) and occurs more often in adults than in children.

**Etiology**

HAV is an RNA virus, a member of the picornavirus family. It is heat stable and has limited host range—namely, the human and other primates.

**Epidemiology**

HAV infection occurs throughout the world but is most prevalent in developing countries. In the United States, 30–40% of the adult population has evidence of previous HAV infection. Hepatitis A is thought to account for approximately 50% of all clinically apparent acute viral hepatitis in the United States. As a result of aggressive implementation of a childhood vaccination strategy, the prevalence of symptomatic HAV cases in the United States has declined significantly. However, outbreaks in day care centers (where the spread from young, nonicteric, infected children can occur easily) as well as multiple foodborne and waterborne outbreaks have justified the implementation of a universal vaccination program.

HAV is highly contagious. Transmission is almost always by person-to-person contact through the fecal–oral route. Perinatal transmission occurs rarely. No other form of transmission is recognized. HAV infection during pregnancy or at the time of delivery does not appear to result in increased complications of pregnancy or clinical disease in the newborn. In the United States, increased risk of infection is found in contacts with infected persons, childcare centers, and household contacts. Infection is also associated with contact with contaminated food or water and after travel to endemic areas. Common source foodborne and waterborne outbreaks have occurred, including several caused by contaminated shellfish, frozen berries, and raw vegetables; no known source is found in about half of the cases. The mean incubation period for HAV is approximately 3 wk. Fecal excretion of the virus starts late in the incubation period, reaches its peak just before the onset of symptoms, and resolves by 2 wk after the onset of jaundice in older subjects. The duration of viral excretion is prolonged in infants. The patient is, therefore, contagious before clinical symptoms are apparent and remains so until viral shedding ceases.

**Clinical Manifestations**

HAV is responsible for acute hepatitis only. Often, this is an anicteric illness, with clinical symptoms indistinguishable from other forms of viral gastroenteritis, particularly in young children.

The illness is much more likely to be symptomatic in older adolescents or adults, in patients with underlying liver disorders, and in those who are immunocompromised. It is characteristic of an acute febrile illness with an abrupt onset of anorexia, nausea, malaise, vomiting, and jaundice. The typical duration of illness is 7–14 days (Fig. 358-1).

Other organ systems can be affected during acute HAV infection. Regional lymph nodes and the spleen may be enlarged. The bone marrow may be moderately hypoplastic, and aplastic anemia has been reported. Tissue in the small intestine might show changes in villous structure, and ulceration of the gastrointestinal tract can occur, especially in fatal cases. Acute pancreatitis and myocarditis have been

reported, though rarely, and nephritis, arthritis, vasculitis, and cryoglobulinemia can result from circulating immune complexes.

**Diagnosis**

Acute HAV infection is diagnosed by detecting antibodies to HAV, specifically, anti-HAV (immunoglobulin [Ig] M) by radioimmunooassay or, rarely, by identifying viral particles in stool. A viral polymerase chain reaction (PCR) assay is available for research use (Table 358-3). Anti-HAV is detectable when the symptoms are clinically apparent, and it remains positive for 4-6 mo after the acute infection. A neutralizing anti-HAV (IgG) is usually detected within 8 wk of symptom onset and is measured as part of a total anti-HAV in the serum. Anti-HAV (IgG) confers long-term protection. Rises in serum levels of ALT, AST, bilirubin, alkaline phosphatase, 5′-nucleotidase, and γ-glutamyl transpeptidase are almost universally found and do not help to differentiate the cause of hepatitis.

**Complications**

Although most patients achieve full recovery, 2 distinct complications can occur. AFL from HAV infection is a rare but not infrequent complication of HAV. Those at risk for this complication are adolescents and adults, but also immunocompromised patients or those with underlying liver disorders. The height of HAV viremia may be linked to the severity of hepatitis. Whereas in the United States, HAV represents <0.5% of pediatric-age ALF, it is responsible for up to 3% mortality in the adult population with ALF. In endemic areas of the world, HAV constitutes up to 40% of all cases of pediatric ALF. HAV can also progress to a prolonged cholestatic syndrome that waxes and wanes over several months. Pruritus and fat malabsorption are problematic and require symptomatic support with antipruritic medications and fat-soluble vitamins. This syndrome occurs in the absence of any liver synthetic dysfunction and resolves without sequelae.

**Treatment**

There is no specific treatment for hepatitis A. Supportive treatment consists of intravenous hydration as needed and antipruritic agents and fat-soluble vitamins for the prolonged cholestatic form of disease. Serial monitoring for signs of ALF and, if ALF is diagnosed, a prompt referral to a transplantation center can be lifesaving.

**Prevention**

Patients infected with HAV are contagious for 2 wk before and approximately 7 days after the onset of jaundice and should be excluded from school, childcare, or work during this period. Careful hand-washing is necessary, particularly after changing diapers and before preparing or serving food. In hospital settings, contact and standard precautions are recommended for 1 wk after onset of symptoms.

**Immunoglobulin**

Indications for intramuscular administration of Ig (0.02 mL/kg) include preexposure and postexposure prophylaxis (Table 358-4).

HAV, hepatitis A virus; HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen; Ig, immunoglobulin; PCR, polymerase chain reaction.

Figure 358-1 The serologic course of acute hepatitis A. ALT, alanine aminotransferase; HAV, hepatitis A virus. (From Goldman L, Ausiello D: Cecil textbook of medicine, ed 22, Philadelphia, 2004, WB Saunders, p 913.)
vaccine preferred in healthy persons 12 mo-40 yr old. An alternative approach is to immunize previously unvaccinated patients who are 12 mo old or older with the age-appropriate vaccine dosage as soon as possible. Ig is not routinely recommended for sporadic nonhousehold exposure (e.g., protection of hospital personnel or schoolmates). The vaccine has several advantages over Ig, including long-term protection, availability and ease of administration, with cost similar to, or less than, that of Ig.

Vaccine
The availability of 2 inactivated, highly immunogenic, and safe HAV vaccines has had a major impact on the prevention of HAV infection. Both vaccines are approved for children older than 12 mo. They are administered intramuscularly in a 2-dose schedule, with the 2nd dose given 6-12 mo after the 1st dose. Seroconversion rates in children exceed 90% after an initial dose and approach 100% after the 2nd dose; protective antibody titer persists for longer than 10 yr in the vast majority of patients. The immune response in immunocompromised persons, older patients, and those with chronic illnesses may be suboptimal; in those patients, combining the vaccine with Ig for pre- and postexposure prophylaxis is indicated. HAV vaccine may be administered simultaneously with other vaccines. A combination HAV and HBV vaccine is approved in adults older than age 18 yr. For healthy persons at least 12 mo old, vaccine is preferable to Ig for preexposure and postexposure prophylaxis (see Table 358-3).

In the United States and some other countries, universal vaccination is now recommended for all children older than 12 mo. Nevertheless, studies show <50% of U.S. adolescents have received 1 dose of the vaccine, and <30% have received the complete vaccine series. The vaccine is effective in curbing outbreaks of HAV because of rapid seroconversion and the long incubation period of the disease.

Prognosis
The prognosis for the patient with HAV is excellent, with no long-term sequelae. The only feared complication is ALF. HAV infection remains a major cause of morbidity; it has a high socioeconomic impact during epidemics and in endemic areas.

Hepatitis B
Etiology
HBV is a member of the Hepadnaviridae family. HBV has a circular, partially double-stranded DNA genome composed of approximately 3,200 nucleotides. Four genes have been identified: the S (surface), C (core), X, and P (polymer) genes. The surface of the virus includes particles designated hepatitis B surface antigen (HBsAg), which is a 22 nm diameter spherical particle and a 22 nm wide tubular particle with a variable length of up to 200 nm. The inner portion of the virion contains hepatitis B core antigen (HbcAg), the nucleocapsid that encodes the viral DNA, and a nonstructural antigen called hepatitis B e antigen (HbeAg), a nonparticulate soluble antigen derived from HbcAg by proteolytic self-cleavage. HbeAg serves as a marker of active viral replication and usually correlates with HBV DNA levels. Replication of HBV occurs predominantly in the liver but also occurs in the lymphocytes, spleen, kidney, and pancreas.

Epidemiology
HBV has been detected worldwide, with an estimated 400 million persons chronically infected. The areas of highest prevalence of HBV infection are sub-Saharan Africa, China, parts of the Middle East, the Amazon basin, and the Pacific Islands. In the United States, the native population in Alaska had the highest prevalence rate before the implementation of universal vaccination programs. An estimated 1.25 million persons in the United States are chronic HBV carriers, with approximately 300,000 new cases of HBV occurring each year, the highest incidence being among adults 20-39 yr of age. One in 4 chronic HBV carriers will develop serious sequelae in their lifetime. The number of new cases in children reported each year is thought to be low but is difficult to estimate because many infections in children are asymptomatic. In the United States, since 1982 when the first vaccine for HBV was introduced, the overall incidence of HBV infection has been reduced by more than half. Since the implementation of universal vaccination programs in Taiwan and the United States, substantial progress has been made toward eliminating HBV infection in children in these countries. In fact, in Alaska, where HBV neared epidemic proportions, universal newborn vaccination with mass screening and immunization of susceptible Alaska Natives virtually eliminated symptomatic HBV and secondary hepatocellular carcinoma.

HBV is present in high concentrations in blood, serum, and serous exudates and in moderate concentrations in saliva, vaginal fluid, and semen. Efficient transmission occurs through blood exposure and sexual contact. Risk factors for HBV infection in children and adolescents include acquisition by intravenous drugs or blood products, contaminated needles used for acupuncture or tattoos, sexual contact, institutional care, and intimate contact with carriers. No risk factors are identified in approximately 40% of cases. HBV is not thought to be transmitted via indirect exposure, such as sharing toys.

### Table 358-4 Hepatitis A Virus Prophylaxis

| PREEXPOSURE PROPHYLAXIS (TRAVELERS TO ENDEMIC REGIONS) |
|---------------------------------|-----------------|
| AGE | EXPECTED EXPOSURE DURATION | DOSE |

*Decision for prophylaxis in nonhousehold contacts should be tailored to individual exposure and risk. Ig, Immunoglobulin.
In children, the most important risk factor for acquisition of HBV remains perinatal exposure to an HBsAg-positive mother. The risk of transmission is greatest if the mother is also HBeAg-positive; up to 90% of these infants become chronically infected if untreated. Intrauterine infection occurs in 2.5% of these infants. In most cases, serologic markers of infection and antigenemia appear 1-3 mo after birth, suggesting that transmission occurred at the time of delivery. Virus contained in amniotic fluid or in maternal feces or blood may be the source. Immunophylaxis with hepatitis B immunoglobulin (HBIG) and the HBV immunization, given within 12 hr of delivery is very effective in preventing infection and protects >95% of neonates born to HBsAg-positive mothers. Of the 22,000 infants born each year to HBsAg-positive mothers in the United States, 98% receive immunophylaxis and are thus protected. Infants who fail to receive the complete vaccination series (e.g., homeless children, international adoptees, and children born outside the United States), however, have the highest incidence of developing chronic HBV. These and all infants born to HBsAg-positive mothers should have follow-up HBsAg and anti-HBs tested to determine appropriate follow-up.

HBsAg is inconsistently recovered in human milk of infected mothers. Breastfeeding of nonimmunized infants by infected mothers does not confer a greater risk of hepatitis than does formula feeding.

The risk of developing chronic HBV infection, defined as being positive for HBsAg for longer than 6 mo, is inversely related to age of acquisition. In the United States, although <10% of infections occurs in children, these infections account for 20-30% of all chronic cases. This risk of chronic infection is 90% in children younger than 1 yr; the risk is 30% for those 1-5 yr and 2% for adults. Chronic infection is associated with the development of chronic liver disease and hepatocellular carcinoma. The carcinoma risk is independent of the presence of cirrhosis and was the most prevalent cancer-related death in young adults in Asia where HBV was endemic.

HBV has 8 genotypes (A-H). A is pandemic, B and C are prevalent in Asia, D is seen in Southern Europe, E in Africa, F in the United States, G in the United States and France, and H in Central America. Genetic variants have become resistant to antiviral agents. After infection, the incubation period ranges from 45-160 days, with a mean of approximately 120 days.

Pathogenesis
The acute response of the liver to HBV is the same as for all hepatotropic viruses. Persistence of histologic changes in patients with hepatitis B indicates development of chronic liver disease. HBV, unlike the other hepatotropic viruses, is a predominantly noncytopathogenic virus that causes injury mostly by immune-mediated processes. The severity of hepatitis injury reflects the degree of the immune response, with the most complete immune response being associated with the greatest likelihood of viral clearance but also the most severe injury to hepatocytes. The 1st step in the process of acute hepatitis is infection of hepatocytes by HBV, resulting in expression of viral antigens on the cell surface. The most important of these viral antigens may be the nucleocapsid antigens HBeAg and HBsAg. These antigens, in combination with class I major histocompatibility proteins, make the cell a target for cytotoxic T-cell lysis.

The mechanism for development of chronic hepatitis is less well understood. To permit hepatocytes to continue to be infected, the core protein or major histocompatibility class I protein might not be recognized, the cytotoxic lymphocytes might not be activated, or some other, yet unknown mechanism might interfere with destruction of hepatocytes. This tolerance phenomenon predominates in the perinatally acquired cases, resulting in a high incidence of persistent infection in children with no or little inflammation in the liver, normal liver enzymes, and markedly elevated HBV viral load. Although end-stage liver disease rarely develops in those patients, the inherent hepatocellular carcinoma risk is very high, possibly related, in part, to uncontrolled viral replication cycles.

ALF has been seen in infants of chronic carrier mothers who have anti-HBc or are infected with a precore-mutant strain. This fact led to the postulate that HBeAg exposure in utero in infants of chronic carriers likely induces tolerance to the virus once infection occurs postnatally. In the absence of this tolerance, the liver is massively attacked by T cells and the patient presents with ALF.

Immune-mediated mechanisms are also involved in the extrahepatic conditions that can be associated with HBV infections. Circulating immune complexes containing HbsAg can result in polyarteritis nodosa, membranous or membranoproliferative glomerulonephritis, polymyalgia rheumatica, leukocytoclastic vasculitis, and Guillain-Barré syndrome.

Clinical Manifestations
Many acute cases of HBV infection in children are asymptomatic, as evidenced by the high carriage rate of serum markers in persons who have no history of acute hepatitis. The usual acute symptomatic episode is similar to that of HAV and HCV infections but may be more severe and is more likely to include involvement of skin and joints (Fig. 358-2). The first biochemical evidence of HBV infection is elevation of serum ALT levels, which begin to rise just before development of fatigue, anorexia, and malaise, which occurs approximately 6-7 wk after exposure. The illness is preceded in a few children by a serum sickness–like prodrome marked by arthralgia or skin lesions, including urticarial, purpuric, macular, or maculopapular rashes. Papular acrodermatitis, the Gianotti-Crosti syndrome, can also occur. Other extrahepatic conditions associated with HBV infections in children include polyarteritis nodosa, glomerulonephritis, and aplastic anemia. Jaundice is present in approximately 25% of acutely infected patients and usually begins approximately 8 wk after exposure and lasts approximately 4 wk.

In the usual course of resolving HBV infection, symptoms are present for 6-8 wk. The percentage of children in whom clinical evidence of hepatitis develops is higher for HBV than for HAV, and the rate of ALF is also greater. Most patients do recover, but the "chronic carrier state" complicates up to 10% of cases acquired in adulthood. The rate of development of chronic infection depends largely on the mode and age of acquisition and occurs in up to 90% of perinatal cases. Chronic hepatitis, cirrhosis, and hepatocellular carcinoma are only seen with chronic infection. Chronic HBV infection has 3 identified phases: immune tolerant, immune active, and inactive. Most children fall in the immune-tolerant phase, against which no effective therapy has been developed. Most treatments target the immune active phase of the disease, characterized by active inflammation, elevated ALT/AST levels, and progressive fibrosis. Spontaneous HBeAg seroconversion, defined as the development of anti-HBe and becoming HBeAg-negative, occurs in the immune-tolerant phase, albeit at low rates of 4-5% per year. It is more common in childhood-acquired HBV rather than in vertically transmitted infections. Seroconversion can occur over many years, during which time significant damage to
the liver may take place. There are no large studies that help accurately assess the lifetime risks and morbidities of children with chronic HBV infection, making the timing of still less-than-ideal treatments ever so hard to decide. Reactivation of chronic infection has been reported in immunosuppressed children (treated with chemotherapy, biologic immunomodulators such as infliximab, T-cell depleting agents), leading to an increased risk of ALF or to rapidly progressing fibrotic liver disease.

**Diagnosis**

The serologic profile of HBV infection is more complex than for HAV infection and differs depending on whether the disease is acute or chronic (Fig. 358-3). Several antigens and antibodies are used to confirm the diagnosis of acute HBV infection (see Table 358-3). Routine screening for HBV infection requires assay of multiple serologic markers (HBsAg, anti-HBc, anti-HBs). HBsAg is the first serologic marker of infection to appear and is found in almost all infected persons; its rise closely coincides with the onset of symptoms. Persistence of HBsAg beyond 6 mo defines the chronic infection state. During recovery from acute infection, because HBsAg levels fall before symptoms wane, IgM antibody to HBcAg (anti-HBc IgM) might be the only marker of acute infection. Anti-HBc IgM rises early after the infection and remains positive for many months before being replaced by anti-HBc IgG, which then persists for years. Anti-HBc is therefore a valuable serologic marker of acute HBV infection. Anti-HBs marks serologic recovery and protection. Only anti-HBs is present in persons immunized with hepatitis B vaccine, whereas both anti-HBs and anti-HBc are detected in persons with resolved infection. HBeAg is present in active acute or chronic infection and is a marker of infectivity. The development of anti-HBe, termed serocconversion, marks improvement and is a goal of therapy in chronically infected patients. HBV DNA can be detected in the serum of acutely infected patients and chronic carriers. High DNA titers are seen in patients with HBeAg, and they typically fall once anti-HBe develops.

**Complications**

Acute liver failure with coagulopathy, encephalopathy, and cerebral edema occurs more commonly with HBV than the other hepatotropic viruses. The risk of ALF is further increased when there is coinfection or superinfection with HDV and in an immunosuppressed host. Mortality from ALF is >30%, and liver transplantation is the only effective intervention. Supportive care aimed at sustaining patients and early referral to a liver transplantation center can be lifesaving. As mentioned, HBV infection can also result in chronic hepatitis, which can lead to cirrhosis, end-stage liver disease complications, and primary hepatocellular carcinoma. Membranous glomerulonephritis with deposition of complement and HBeAg in glomerular capillaries is a rare complication of HBV infection.

**Treatment**

Treatment of acute HBV infection is largely supportive. Close monitoring for liver failure and extrahepatic morbidities is key.

Treatment of chronic HBV infection is in evolution; no one drug currently achieves consistent, complete eradication of the virus. The natural history of HBV chronic infection in children is complex, and there is a lack of reliable long-term outcome data on which to base treatment recommendations. Treatment of chronic HBV infection in children should be individualized and done under the care of a pediatric gastroenterologist experienced in treating liver disease.

The goal of treatment is to reduce viral replication defined by having undetectable HBV DNA in the serum and development of anti-HBe, termed serocversion. The development of anti-HBe transforms the disease into an inactive form, thereby decreasing infectivity, active liver injury and inflammation, fibrosis progression, and the risk of hepatocellular carcinoma. Currently, treatment is only indicated for patients in the immune-active form of the disease, as evidenced by elevated ALT and/or AST, who have fibrosis on liver biopsy, putting the child at higher risk for cirrhosis during childhood.

**Treatment Strategies**

*Interferon-α2b (IFN-α2b)* has immunomodulatory and antiviral effects. It has been used in children, with long-term viral response rates similar to the 25% rate reported in adults. Interferon (IFN) use is limited by its subcutaneous administration, treatment duration of 24 wk, and possible side effects (flu-like symptoms, marrow suppression, depression, retinal changes, autoimmune disorders). IFN is further contraindicated in decompensated cirrhosis. One advantage of IFN, compared to other treatments, is that viral resistance does not develop with its use.

*Lamivudine* is an oral synthetic nucleoside analog that inhibits the viral enzyme reverse transcriptase. In children older than age 2 yr, its use for 52 wk resulted in HBeAg clearance in 34% of patients with an ALT > 2 times normal; 88% remained in remission at 1 yr. It has a good safety profile. Lamivudine has to be used for ≥6 mo after viral clearance, and the emergence of a mutant viral strain (YMDD) poses a barrier to its long-term use. Combination therapy in children using IFN and lamivudine did not seem to improve the rates of response in most series.

*Adefovir* (a purine analog that inhibits viral replication) is approved for use in children older than 12 yr of age, in whom a prospective 1-year study showed 23% serocconversion. No viral resistance was noted in that study but has been reported in adults.

*Entecavir* (a nucleoside analog that inhibits replication) is currently approved for use in children older than age 16 yr. Prospective data has shown a 21% serocconversion rate in adults with minimal resistance developing. Patients in whom resistance to lamivudine developed, have an increased risk of resistance developing to entecavir.

*Tenofovir* (a nucleotide analog that inhibits viral replication) is also approved for use in children older than age 16 yr. Data have shown efficacy in children older than age 12 yr. Prospective data have shown a 21% serocconversion rate with a very low rate of resistance developing. Patients with lamivudine-resistant mutations do not appear to have an increased rate of resistance. Concern exists over long-term use and bone mineral density.

*Peginterferon-α*, has the same mechanism of action as IFN, but is given once weekly. This formulation has not been approved in the United States but is recommended for the treatment of chronic HBV in other countries. Patients most likely to respond to currently available drugs have low serum HBV DNA titers, are HBeAg-positive, have active hepatic inflammation (ALT greater than twice the upper limit of normal for at least 6 mo), and recently acquired disease.

Immune tolerant patients—those with normal ALT and AST, who are HBeAg-positive with elevated viral load—are currently not considered for treatment, although the emergence of new treatment...
paradigms are promising for this large, yet hard-to-treat, subgroup of patients.

**Prevention**

The most effective prevention strategies have resulted from the screening of pregnant mothers and the use of HBIG and hepatitis B vaccine in infants as noted earlier. In HBsAg-positive and HBeAg-positive mothers, a 10% risk of chronic HBV infection exists compared to 1% in HBeAg-negative mothers. This knowledge offers screening strategies that may affect both mother and infant through the use of antiviral medications during the 3rd trimester. Recent guidelines suggest that mothers with a HBV DNA viral load $>$200,000 IU/mL receive an antiviral such as telbivudine, lamivudine, or tenofovir during the 3rd trimester, especially if they had a previous child who developed chronic HBV after receiving HBIG and the hepatitis B vaccine.

Household, sexual, and needle-sharing contacts should be identified and vaccinated if they are susceptible to HBV infection. Patients should be advised about the perinatal and intimate contact risk of transmission of HBV. HBV is not spread by breastfeeding, kissing, hugging, or sharing water or utensils. Children with HBV should not be excluded from school, play, childcare, or work, unless they are prone to biting. A support group might help children to cope better with their disease. Families should not feel obligated to disclose the diagnosis as this information may lead to prejudice or mistreatment of the patient or the patient’s family. All patients positive for HBsAg should be reported to the state or local health department, and chronicity is diagnosed if they remain positive past 6 mo.

**Hepatitis B Immunoglobulin**

HBIG is indicated only for specific postexposure circumstances and provides only temporary protection (3-6 mo; Table 358-5). It plays a pivotal role in preventing perinatal transmission when administered within 12 hr of birth.

**Universal Vaccination**

In 2005, the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices revised its recommendations regarding HBV vaccination. These recommendations have been incorporated into the American Academy of Pediatrics Vaccine schedule. A main focus is universal infant vaccination, beginning at birth, to provide a safety net for preventing perinatal infection, prevent early childhood infection, facilitate implementation of universal vaccine recommendations, and prevent infection in adolescents and adults. The ultimate goal is to eliminate HBV transmission in the United States and to integrate HBV vaccination in a harmonized childhood vaccination.

Two single-antigen vaccines (Recombivax HB and Engerix-B) are approved for children and are the only preparations approved for infants younger than age 6 mo. Three combination vaccines can be used for subsequent immunization dosing and enable integration of the HBV vaccine into the regular immunization schedule. The safety profile of HBV vaccine is excellent. The most reported side effects are pain at the injection site (up to 29% of cases) and fever (up to 6% of cases). Seropositivity is $>$95% with all vaccines, achieved after the 2nd dose in most patients. The 3rd dose serves as a booster and may have an effect on maintaining long-term immunity. In immunosuppressed patients and infants whose birthweight is $<$2,000 g, a 4th dose is recommended, as is checking for seroconversion. Despite declines in the anti-HBs titer in time, most healthy vaccinated persons remain protected against HBV infection.

Current HBV vaccination recommendations are as follows (see Table 358-5):

- Infants born to HBsAg-negative mothers:
  - For all medically stable infants weighing $>$2,000 g at birth and born to HBsAg-negative mothers, the 1st dose of HBV vaccine should be administered before hospital discharge. Single-dose antigen HBV vaccine should be used for the birth dose. Subsequent doses to complete the series are given at 1−4 mo and at 6−18 mo of age. Routine postvaccination testing of immunized infants born to HBsAg-negative women or with anti-HBs is not recommended.
  - In rare circumstances (on a case-by-case basis), the 1st dose may be delayed (up to 2 mo) until after hospital discharge. When a decision to delay is made, however, a physician’s order to withhold the birth dose, along with a copy of the original laboratory report indicating that the mother was HBsAg-negative, should be placed on the medical record.

*Both HBIG and vaccine should be administered within 12 hr of the infant’s birth and within 24 hr of identifiable blood exposure. HBIG can be given up to 14 days after sexual exposure.

†HBIG dose: 0.5 µL for newborns of HBsAg-positive mothers, and 0.06 µL/kg for all others when recommended.

‡Seroconversion status of immunocompromised patients should be checked 1-2 mo after the last dose of vaccine, and yearly thereafter. Booster doses of vaccine should be administered if the anti-HBs titer is $<$10 mIU/mL. Nonresponsive patients should be considered at high risk for HBV acquisition and counseled about preventive measures.

HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.
Preterm infants weighing <2,000 g at birth and born to HBsAg-negative mothers should have their initial dose delayed until 1 mo of age or before hospital discharge.

To increase coverage of children and adolescents not previously vaccinated, many states have made immunization a requirement for entry into junior high school (middle school).

Infants born to HBsAg-positive or HBsAg-unknown mothers:

To prevent perinatal transmission through improved maternal screening and immunoprophylaxis, infants born to HBsAg-positive women should receive vaccine at birth, 1–2 mo, and 6 mo of age (see Table 358-4). The 1st dose should be accompanied by administration of 0.5 mL of HBIG as soon after delivery as possible (within 12 hr) because the effectiveness decreases rapidly with increased time after birth.

If mother’s HBsAg status is unknown, the vaccine should be administered within 12 hr of birth regardless of birthweight. For infants weighing <2,000 g, HBIG and the HBV vaccine should be administered within 12 hr of birth. The mother’s HBsAg status should be administered as soon as possible and, if she is HBsAg-positive, HBIG should be given for infants weighing ≥2,000 g (no later than 1 wk).

Postvaccination testing for HBsAg and anti-HBs should be done at 9–18 mo. If the result is positive for HBsAg, the child is immune to HBV. If the result is positive for HBsAg only, the parent should be counseled and the child evaluated by a pediatric gastroenterologist. If the result is negative for both HBsAg and anti-HBs, a second complete hepatitis B vaccine series should be administered, followed by testing for anti-HBs to determine if subsequent doses are needed.

Administration of 4 doses of vaccine is permissible when combination vaccines are used after the birth dose; this does not increase vaccine response.

Postexposure Prophylaxis

Recommendations for postexposure prophylaxis for prevention of hepatitis B infection depend on the conditions under which the person is exposed to HBV (see Table 358-5). Vaccination should never be postponed if written records of the exposed person’s immunization history are not available, but every effort should still be made to obtain those records.

Special Populations

Patients with cirrhosis may not respond as well to the HBV vaccine and repeating anti-HBs titers should be performed. Adult studies suggest higher dosage or shorter interval between dosages may increase the immunization effectiveness. Recent evidence has shown patients with inflammatory bowel disease frequently have not been immunized, or did not develop complete immunity to HBV, as demonstrated by inadequate anti-HBs levels. These patients may be at risk for fulminant HBV when immunosuppression is started as part of their treatment regimen, specifically with biologic agents such as infliximab.

Prognosis

In general, the outcome after acute HBV infection is favorable, despite a risk of ALF. The risk of developing chronic infection brings the risks of liver cirrhosis and hepatocellular carcinoma to the forefront. Perinatal transmission leading to chronicity is responsible for the high incidence of hepatocellular carcinoma in young adults in endemic areas. Importantly, HBV infection and its complications are effectively controlled and prevented with vaccination and multiple clinical trials are ongoing in an effort to improve and guide treatment regimens.

HEPATITIS C

Etiology

HCV is a single-stranded RNA virus, classified as a separate genus within the Flaviviridae family, with marked genetic heterogeneity. It has 6 major genotypes and numerous subtypes and quasi-species, which permit the virus to escape host immune surveillance. Genotype variation might partially explain the differences in clinical course and response to treatment. Genotype 1b is the most common genotype in the United States and is the least responsive to the currently available medications.

Epidemiology

In the United States, HCV infection is the most common cause of chronic liver disease in adults and causes 8,000–10,000 deaths per year. Approximately 4 million people in the United States and 170 million people worldwide are estimated to be infected with HCV. Approximately 85% of infected adults remain chronically infected. In children, seroprevalence of HCV is 0.2% in those younger than age 11 yr and 0.4% in children age 11 yr or older. However, even more children may be infected as only a small percentage of HCV-infected children are identified, and an even smaller number subsequently receive treatment. Appropriate identification, and screening, for infected individuals should be implemented.

Risk factors for HCV transmission in the United States included blood transfusion before 1992 as the most common route of infection, but, with current screening practices, the risk of HCV transmission is approximately 0.001% per unit transfused. Illegal drug use with exposure to blood or blood products from HCV-infected persons accounts for more than half of adult cases in the United States. Sexual transmission, especially through multiple sexual partners, is the second most common cause of infection. Other risk factors include occupational exposure, but approximately 10% of new infections have no known transmission source. In children, perinatal transmission is the most prevalent mode of transmission (see Table 358-1). Perinatal transmission occurs in up to 5% of infants born to viremic mothers. HIV coinfection and high viremia titers (HCV RNA-positive) in the mother can increase the transmission rate to 20%. The incubation period is 7–9 wk (range: 2–24 wk).

Pathogenesis

The pattern of acute hepatic injury is indistinguishable from that of other hepatotropic viruses. In chronic cases, lymphoid aggregates or follicles in portal tracts are found, either alone or as part of a general inflammatory infiltrate of the portal areas. Steatosis is also often seen in these liver specimens. HCV appears to cause injury primarily by cytopathic mechanisms, but immune-mediated injury can also occur. The cytopathic component appears to be mild, because the acute illness is typically the least severe of all hepatotropic virus infections.

Clinical Manifestations

Acute HCV infection tends to be mild and insidious in onset (Fig. 358-4; see also Table 358-1). ALF rarely occurs. HCV is the most likely cause of ALF when other causes have been excluded.

Figure 358-4 The serologic course of acute hepatitis C. ALT, alanine aminotransferase; HCV, hepatitis C virus; PCR, polymerase chain reaction. (From Goldman L, Ausiello D: Cecil textbook of medicine, ed 22, Philadelphia, 2004, WB Saunders, p. 915.)
hepatotropic virus to cause chronic infection (Fig. 358-5). Of affected adults, <15% clear the virus; the rest develop chronic hepatitis. In pediatric studies, 6-19% of children achieved spontaneous sustained clearance of the virus during a 6 yr follow-up. Chronic HCV infection is also clinically silent until a complication develops. Serum aminotransferase levels fluctuate and are sometimes normal, but histologic inflammation is universal. Progression of liver fibrosis is slow over several years, unless comorbid factors are present, which can accelerate fibrosis progression. Approximately 25% of infected patients ultimately progress to cirrhosis, liver failure, and, occasionally, primary hepatocellular carcinoma (HCC) within 20-30 yr of the acute infection. Although progression is rare within the pediatric age range, cirrhosis and HCC from HCV have been reported in children. The long-term morbidities constitute the rationale for diagnosis and treatment in children with HCV.

Chronic HCV infection can be associated with small vessel vasculitis and is a common cause of essential mixed cryoglobulinemia. Other extrahepatic manifestations, predominantly seen in adults, include cutaneous vasculitis, peripheral neuropathy, cerebritis, membranoproliferative glomerulonephritis, and nephrotic syndrome. Antibodies to smooth muscle, antinuclear antibodies, and low thyroid hormone levels may also be present.

**Diagnosis**
